ABSTRACT

Subtropical deforestation in Latin America is thought to be driven by demand for agricultural land, particularly to grow soybeans. However, existing remote sensing methods that can differentiate crop types to verify this hypothesis require high spatial or spectral resolution data, or extensive ground truth information to develop training sites, none of which are freely available for much of the world. I developed a new method of crop classification based on the phenological signatures of crops extracted from multi-temporal MODIS vegetation indices. I tested and refined this method using the USDA Cropland Data Layer from Kansas, USA as a reference. I then applied the method to classify crop types for a study site in Pellegrini, Santiago Del Estero, Argentina. The results show that this method is unable to effectively separate summer crops in Pellegrini, but can differentiate summer crops and non-summer crops well. Unmet assumptions about agricultural practices are primarily responsible for the ineffective summer crop classification, underlining the need for researchers to have a complete understanding of ground conditions when designing a remote sensing analysis.

Acknowledgements

I could not have completed this project without the help and support of many who have come along side me in this endeavor. Firstly, thanks to my advisor, Geoffrey Duh, for his guidance, insights, and many hours of dedicated assistance. I would not have even known what I was proposing to do without him making sense of my ramblings. Thank you to my thesis committee members Leopoldo Rodriguez and David Banis, to whom I am grateful for their contributions. Polo, that shovel saved me. Thank you to Martha Works, for her input and direction with my research into understanding my topic from a cultural geography perspective. Thank you Karin Walker and to other staff in the department who helped me navigate the complex bureaucracy of PSU. Thanks to all in my cohort for their support and camaraderie, in particular Tony Hair for his putting up with my incessant, overly-technical geo-babble, and encouraging me to continue even when I wanted to stop.

I must also extend a big thank you to Joe Poracsky and the PSU Geography Department, whose generosity help make this project possible.

Thank you to all those outside of PSU for their encouragement and support through this project: my parents, La Familia Flores, Aaron and Catherine, Tom and Harmony, Josh and Rachel, Matt and Jesse, Renjy and Katy, Dean, Carlos...the list goes on.

To the people of Pellegrini: Gracias a todos. No puedo creer como la gente me ayudaron, especialmente Roberto y Manuel Dantas, David Ruiz, Rafael Dip, y Martín Lasko. Es verdad, sin ustedes yo no haya tenido éxito. Muchas gracias. Espero que yo puede regresar a Nueva Esperanza otra vez. Es una lugar especial a mi, por la gente. Y Playmax, es la gravedad: no me puedo resistir la atracción.

Lastly, but definitely not least, thank you to my wife Aida. You have stood by me through the whole of this process, encouraging and pushing me to continue even when it made life more difficult for you. Te debo. Te quiero, mi bella.

Chapter 1

Introduction

Deforestation has long been a concern throughout tropical South America. However, this process of land use/land cover (LULC) change from forest to other uses has been increasingly recognized in subtropical South America as a significant source of environmental degradation. Understanding the complex dynamics of subtropical deforestation is crucial given the prominent role of forests in debates about climate change, conservation, and the protection of endangered species (Geist and Lambin 2002; Zak, Cabido, and Hodgson 2004; Bonnie 2000; Houghton 1994; Sala et al. 2000).

Currently, many perceive growing demand for agricultural land—particularly land for soybeans—to be one of the greatest pressures on South American subtropical forests (Pengue 2005; Grau, Gasparri, and Aide 2005; Altieri and Pengue 2006). Remote sensing has given researchers a tool to classify land cover and measure deforestation, but the often used multi-spectral or multi-temporal image classification techniques require extensive ground truth information for the accurate classification of common crop types using widely-available remotely-sensed data. Therefore, getting a complete picture of the dynamics of deforestation, including an understanding of agricultural pressures on forests, requires rarely-

available high spatial or high spectral resolution data (Senay et al. 2000) or expensive field time gathering training site data. The development of a tool that can efficiently and effectively extract crop types using widely-available imagery would be of value in investigations of LULC change in areas under rapid agricultural expansion.

The primary goal of this thesis is to develop and test a phenological classification toolset that can identify and extract crop types from a multi-date vegetation index sequence assembled using free and publicly-accessible data from the National Aeronautics and Space Administration's (NASA) Moderate Resolution Imaging Spectroradiometer (MODIS) sensor. The toolset was tested using the U.S. Department of Agriculture's (USDA) Cropland Data Layer (CDL) from a test field in Kansas, USA. The CDL data provided delineation and crop identification of agricultural fields in the study area. Overlaid on the MODIS data, the CDL crop boundaries allowed extraction of reference phenological signatures of various summer crops. Using the Kansas-derived reference signatures, imagery of the 2014 summer growing season in the Department of Pellegrini, Santiago del Estero, Argentina was then classified with the toolset. I further preformed a classification accuracy assessment to examine the toolset's applicability in subtropical South America.

The body of this thesis is broken into seven chapters. The first chapter gives an overview and an introduction of the research. The second chapter provides background information on deforestation and soybean cultivation in Argentina. The third introduces the two study areas where the processing methods, presented in Chapter 4, are applied. Chapter 5 reviews the results of said methods, and Chapter 6 is a discussion of their significance. Chapter 7 closes the thesis with some concluding remarks.

An additional five appendices contain supporting information. Appendix A is a reflection of my time in Argentina doing the fieldwork for this project. Appendix B documents the toolset created to implement the processing methods of Chapter 4 and the development process. All the initial testing of the tools is reviewed in Appendix C. Appendix D contains a collection of ideas for future testing and research. Lastly, Appendix E is a brief note about the CDL dataset.

Chapter 2

Background

2.1 Deforestation and the *Ley de Bosques* (Forest Act) in Argentina

The conversion of forestland to other uses has seriously impacted Argentina's forests. In 1915 it was remarked that 30 percent of the country had forest cover, but in 2001 only 10 percent remained forested (Secretaría de Desarrollo Sustentable y Política Ambiental [Argentina] 2001). Over the period 1998 to 2002, Argentina lost over 940,000 hectares of forest cover (Secretaría de Ambiente y Desarrollo Sustentable [Argentina] 2007). The high rate of deforestation concerned policymakers, and Law 26.331, or the *Ley de Bosques* (Forest Act), was voted into law in 2007 in an effort to preserve remaining native forests. Areas of native forest are defined to be those with forest cover of at least 20 percent native species, and that have trees of a minimum of 7 meters high. The law designates red, yellow, and green areas, each with different restrictions on clearing and use. Red is assigned to areas of "high conservation value," yellow is for areas that must be managed sustainably, and green allows "partial or total use" (Gulezian 2009: 25). Each provincial government was responsible for determining how to classify their native forest area, and each enacted the *Ley de Bosques*

regulations under the *Ordenamiento Territorial de los Bosques Nativos* (Land Management Order for Native Forests, OTBN).

As a part of Law 26.331, ongoing land cover studies are done to examine the effectiveness of the legislation. Between 2006 and the passing of the law, 573,296 hectares of native forest cover were lost. From the passing of the law in 2007 and the classification of the OTBN areas in 2009, a further 473,001 hectares were deforested. From the enacting of the OTBN (in 2009) and 2011, some 459,108 hectares were found to have been lost (Secretaría de Ambiente y Desarrollo Sustentable [Argentina] 2012). The continued deforestation suggests that, in the context of the native forest areas, the *Ley de Bosques* may have had a small effect in reducing deforestation, but overall levels still remain quite high. Consequently, some have begun to question the effectiveness of the law at slowing cutting (Valpreda 2012; Greenpeace Argentina 2013). Clearly, a better understanding of the driving forces of deforestation in Argentina needs to be developed.

2.2 Soy and its effects

The increase of soybean in Argentina has occurred at a rapid pace throughout the last two decades, making it the third largest producer of soy in the world (U.S. Foreign Agricultural Service 2013). Necessarily, as soy production rises, so does its spatial extent and the intensity of cultivation methods. Currently, almost all of Argentina's soy production is using genetically modified (GM) varieties, specifically Monsanto's "Roundup Ready" beans (Greenpeace International 2005). The highly mechanized and input intensive nature of this crop type calls into question other environmental consequences of soybean cultivation,

such as pesticide runoff, glyphosate-resistant weeds, and soil depletion (Pengue 2005). The significant capital expense for such mechanical and chemical technologies is consolidating land ownership as small famers find themselves unable to compete with larger producers' economies of scale.

A number of studies have addressed soy and deforestation in Northwest Argentina, but only one has used methods capable of mapping crop types in deforested areas (Volante et al. 2005). However, this study by the Argentine *Instituto Nacional de Tecnología Agropecuaria* (National Institute of Agricultural Technology, INTA) does not have well-documented methodology and has not been updated since 2005. Of the remainder, all used remote sensing techniques to classify only LULC and not specific crop types, leaving the effect of soy on LULC as an underlying assumption (Grau, Gasparri, and Aide 2005, 2008; Grau, Aide, and Gasparri 2005; Boletta et al. 2006; Gasparri and Grau 2009). While the extreme deforestation in Argentina is undeniable—and certainly soy plays a part—its role has not been examined in full, leaving unsubstantiated the perception of soy as the driving force in this process.

The goal of this research is to develop an image classification method capable of mapping agricultural crops by type, allowing soy to be explicitly identified on remotely sensed imagery. The accurate and efficient mapping of soy distributions and their changes over time could allow further investigation of the roles of soy in deforestation. The direct and indirect effects soy crops have had on deforestation can thus be understood conceptually and systemically at both regional and local scales, which could lead to the development of more effective policies for land management (Brown et al. 2007).

2.3 Composite Vegetation Indices and Time-Series Images

The differentiation of crop types in remotely-sensed imagery is not a straightforward process. The use of a vegetation index (VI), such as the normalized difference vegetation index (NDVI) or the enhanced vegetation index (EVI), can help identify crops by their specific VI values in an image.

NDVI is a normalized ratio of the red and near-infrared bands, and can be expressed mathematically as:

$$NDVI = \frac{\rho_{NIR} - \rho_{red}}{\rho_{NIR} + \rho_{red}} \quad (2.1)$$

where ρ_{NIR} and ρ_{red} are the measured surface reflectance in their respective bands. As a ratio, the index minimizes multiplicative noise, but has issues with non-linearity and additive noise (Huete et al. 2002).

With advances in calibration, atmospheric correction, and other noise removal techniques, which are integrated into the MODIS data processing workflow, a ratioing index is less necessary. The EVI was specifically developed for the MODIS platform to help correct some of the deficiencies of the NDVI. It has better sensitivity to high biomass, canopy structure, and leaf area, and less susceptibility to atmospheric degradation. EVI is calculated as:

$$EVI = G \frac{\rho_{NIR} - \rho_{red}}{\rho_{NIR} + C_1 \times \rho_{red} - C_2 \times \rho_{blue} + L} \quad (2.2)$$

Again, each ρ is the measured surface reflectance in the respective band, after complete or partial atmospheric correction. The blue band is used to “subtract” aerosol effects from the red band. Additionally, four coefficients are introduced: G is the gain factor, C_1 and C_2 are

used in the aerosol calculation, while L “is the canopy background adjustment that addresses nonlinear, differential NIR and red radiant transfer through a canopy” (Huete et al. 2002: 196). The values of these coefficients as used in the MODIS EVI calculation are 2.5, 6.0, 7.5, and 1.0, respectively.

Some crops, such as soy and sugarcane, have very different spectral reflectance throughout their development and maturation, however others, such as soy and corn, can have very similar reflective curves, leading to overlapping VI ranges (Price 1994). Such overlap can make it impossible to determine a crop type with specificity using traditional approaches; even using hyperspectral data, few differentiating characteristics between crops can hinder classification. To combat this ambiguity, a time series of images can be used to find VI values throughout a year, allowing the development of a classifier based on annual phenology rather than a single-date image (Gu et al. 2010; Wardlow and Egbert 2002, 2005; Wardlow, Egbert, and Kastens 2007; Wardlow and Egbert 2008; Zhang et al. 2003). Figure 2.1 shows an example of how the VI values change over a growing season.

MODIS 16-day VI composite imagery from both the Terra and Aqua Earth Observing System (EOS) satellites is available from the Land Processes Distributed Active Archive Center (LPDAAC).¹ Each MODIS satellite images the entire Earth daily: the Terra satellite makes its passes in the morning, while Aqua follows in the afternoon. This temporal resolution is the greatest advantage of the MODIS platform, as the likelihood of getting enough cloud-free data to develop a phenologic model is significantly increased over other common platforms like Landsat Thematic Mapper (TM) and Landsat Operational Land Imager (OLI), which only have repeat coverage every sixteen days. MODIS data, however,

December 19, 2013

February 2, 2014

April 7, 2014

Figure 2.1. Example VI Progression

These MODIS NDVI images show the progression of VI values for a section of a MODIS tile containing the north half of Pellegrini and the surrounding area. The relative constant values for the forested areas stand in stark contrast to the fields, which predominately begin with low VI values in the first image, increasing as the crops mature to the greater values shown in the last image.

comes at the price of a reduced spatial resolution of 231 meters compared to Landsat's 30-meter pixels.² At this resolution, crop mapping is restricted to medium farms and larger—those with fields of at least 250 meters square, though often a field must be up to two times larger in at least one dimension to ensure a pure pixel can be isolated. For the purposes of this investigation, however, this limitation is inconsequential, as small farms have a relatively minor impact on deforestation due to their size. Moreover, the crop of interest, GM soy, is only profitably grown using highly mechanized, input-intensive agricultural practices at very large scales (Kaimowitz and Smith 2001). Small fields do not have high enough yields to overcome the significant capital investment required.

LPDAAC creates the VI composites using the maximum VI value over the proceeding 16-day time period. The images are numbered by the day of the year (DOY) of the last date in the image's date range, so an image from DOY 17 is the composite of the images from 1 January through 17 January.³ Both NDVI and EVI are included in the MODIS VI products, and require no preprocessing for immediate use (unless cloud cover is pervasive in the area). A chronological series of these VIs can be assembled into a time series image (TSI), which can then be used for processing.

2.4 Crop Phenologies and Phenological Classification

Gu et al. outlined that phenological statistics regarding vegetation development can be derived from a MODIS VI time-series, including “start-of-season time (SOST), start-of-season NDVI (SOSN), end-of-season time (EOST), end-of-season NDVI (EOSN), maximum NDVI (MAXN), maximum NDVI time (MAXT), duration of season (DUR), ampli-

tude of NDVI (AMP), and seasonal time integrated NDVI (TIN)” (2010: 529). A principal component analysis (PCA) can then be used to extract the meaningful variation in the data.

Similarly, Wardlow, Egbert, et al. (Wardlow and Egbert 2002, 2005; Wardlow, Egbert, and Kastens 2007; Wardlow and Egbert 2008) showed that a decision tree classifier can be used to classify vegetation time-series data into increasingly refined categories until specific crop types are isolated and classified. By beginning with a basic land cover classification (e.g. forest, urban, agriculture), crops in the agriculture class can be broken down into winter and summer varieties using peaks in the vegetation index (winter wheat will peak earlier in the year than summer crops like corn and soy). Then, using training sites of known crop types defined by ground truth data, a final crop classification can be assigned by finding pixel values for key dates where like crops can be differentiated. That is, using the growing season in the Northern Hemisphere as an example, if from the training sites we know crop A has VI values between 0.7 and 0.8 on June 26 and between 0.5 and 0.6 on August 29, while crop B is between 0.55 and 0.65 and 0.75 and 0.85 on the same dates, pixels in the summer crop class can be assigned one of these types by testing their pixel values on these dates. While the authors found this method to have about an 85 percent overall accuracy (Wardlow and Egbert 2005), the downside of this method is that it requires training sites with previously-determined crop types to produce a classification, which can be time consuming and expensive to acquire.

Masialeti, Egbert, and Wardlow (2010) found that VI values from one year have a significant correlation with values from other years. Comparing the phenological curves of crops formed by the NDVI values from 2001 MODIS data (from Wardlow and Egbert 2005) with

those from 2005 MODIS data, the authors found the overall shape of each crop's curve is maintained year-to-year, with a subtle shift in the beginning of the curve (earlier or later planting), a scaling of the maximum of the curve (better or worse crop development), and scaling of the spread of the curve (a longer or shorter growing season), depending on weather and other external variables (Figure 2.2). They surmised, with a means to account for the shift and scaling of the curve, one could use VI values from one year to classify those from another.

Even without a mechanism to account for interannual differences, Brown et al. (2007) used crop phenologies derived from multiple years of data to test four phenological classification methods. The authors fit the known phenologies to the unknown phenologies from other years by comparing the VI values throughout the growing season. The degree of likeness between a known VI curve and the unknown VI curve determined the classification. They showed that the best of the four classification methods was to find the sum of the square errors between the known and unknown curves (the SSE method, Brown et al. pg. 131).

The similarities between the methods presented in Brown et al. and hyperspectral remote sensing techniques are striking. Hyperspectral techniques compare known spectral *signatures* from a signature library to the unknown pixel signatures in an image. One method, spectral feature fitting, uses a least-squares comparison reminiscent of SSE from Brown et al. (Exelis Visual Information Solutions 2013; Clark et al. 2003). The key difference between the two, besides comparing reflectance across time versus reflectance across the electromagnetic spectrum, is that spectral feature fitting does not require any training data from the

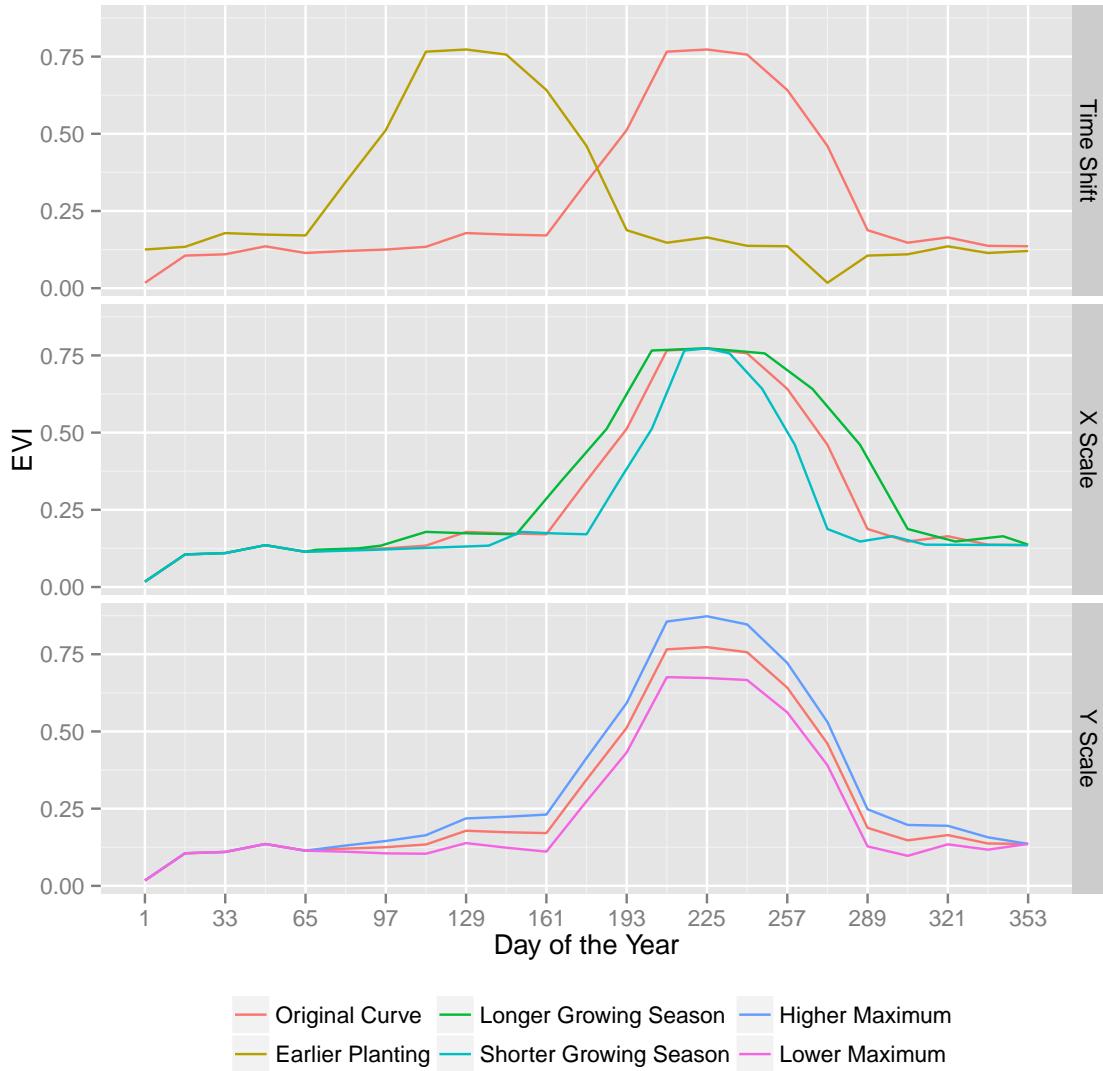

Figure 2.2. Example Transformations of a Crop's VI Curve

The original signature was derived from soy in southwestern Kansas. The other signatures were arbitrarily adjusted to illustrate each of the possible transformations (the diagrams were created by me for illustration purposes).

processed image. All of the spectral signatures used for identification are from standardized spectral libraries, which contain the many spectra of different materials.

Accordingly, one goal of this study is to realize a method of vegetation classification using multi- or hyper-temporal imagery that does not require training data to be extracted from the imagery itself, rather relying on standard libraries of phenological curves—*temporal* signatures—for different vegetation and non-vegetation land covers. A major challenge of this idea is that, unlike spectral signatures, temporal signatures are not necessarily consistent location to location, nor year to year as mentioned above. A viable classification method thusly must provide a way to transform the temporal signatures, within appropriate bounds, to match the horizontal scaling, vertical scaling, and time shifting of an unknown pixel before finding the degree of fit between the signature curve and the pixel curve.

Sakamoto et al. (2005, 2010) demonstrates a method using MODIS time-series data for use in finding key dates in a crop’s phenology, enabling better crop management strategies. Specifically, the authors’ two-step filter (TSF) method uses a wavelet transformation and a constrained minimization function to find a reference signature for a specific crop’s phenological development, and then fits that signature to known pixels of that crop type, finding the scaled dates of key transitions between developmental stages in the plants’ growth. This TSF method demonstrates that reference signatures can be fit to a pixel’s signature using a minimization function, accounting for the variations from the reference curve and the pixel curve. This minimization method provides the means to account for the scaling and time shift differences, allowing previously-known temporal signatures (e.g. not from training sites) to be fit to pixel signatures in a TSI.

Specifically, from page 2151 of Sakamoto et al. (2010):

$$RMSE = \left[\frac{1}{365/s} \sum_{x=j(0), j(1)\dots}^n (f(x) - g(x))^2 \right]^{\frac{1}{2}} \quad (2.3)$$

where n is the number of dates in the TSI, $f(x)$ is the temporal signature for a given pixel in a dataset, and x is the DOY, as defined by $j(y)$:

$$j(y) = k(i \cdot s(y - 1)) \quad (2.4a)$$

$$\text{where } k(z) = \begin{cases} z, & \text{if } z \leq 0 \\ (z \bmod 365) \bmod i - 1, & \text{if } z > 0 \end{cases} \quad (2.4b)$$

such that s is the interval of the imagery and d is the starting date of the imagery. $g(x)$ in Equation 2.3 is given by:

$$g(x) = yscale \times h(xscale \times (x + tshift)) \quad (2.5)$$

Here, x again is the DOY, $yscale$ and $xscale$ are coefficients controlling the vertical and horizontal scaling of a reference signature $h(x)$, and $tshift$ is a constant representing the horizontal shift, in days, of $h(x)$. In other words, $yscale$ adjusts the reference signature to match the growth condition (i.e. maximum VI value) of the pixel (again, given by $f(x)$); $xscale$ adjusts the reference signature to match the pixel's growth cycle duration; and $tshift$, or time-shift, is the offset, in days, between the peak date of the reference signature and the peak date the pixel (see Figure 2.2). Thus, if we minimize Equation 2.3 bounding $yscale$, $xscale$, and $tshift$ in $g(x)$ with reasonable values for each, we can calculate how well a given reference temporal signature $h(x)$ can be made to fit the pixel signature $f(x)$. Comparing a pixel's RMSE value

from each of the reference signatures allows final classification; the signature with the lowest RMSE value has the best fit, and, of the tested signatures, provides the most probable identification.

Notes

¹For those interested in working with MODIS data, the web address of LPDAAC is <https://lpdaac.usgs.gov/>, though data are not directly available from their servers without an exact link. I found the best tool for searching the available data was NASA's Reverb|Echo web tool, at <https://reverb.echo.nasa.gov/>. Using this tool, one can get a list of links in a text file, and can use wget or curl to bulk download the files in the list.

²Though the literature typically denotes MODIS data as 250-meter, the composite vegetation indices are actually 231-meter. However, to stay consistent with conventions, I will refer to the data as 250-meter.

³Following this pattern exactly will make the first image from the following year be from 4 January, but the MODIS composite numbering "resets" at the end of each year. Thus the image interval at the end of the year is shortened, allowing the next image to be produced 1 January, though it still covers the proceeding 16 days.

Chapter 3

Study Areas

This study used agricultural areas in Kansas, USA for testing and verification of the phe-nological classification method and applied the classification method to Pellegrini, Santiago del Estero, Argentina to test its effectiveness in subtropical South America.

3.1 Kansas, USA

The state of Kansas is one of the big agricultural producers of the U.S. As one of the plains states, it is relatively flat across much of its extent, making it well suited to large highly-mechanized agro-industrial operations. In 2012, the three most extensive crops in the state were wheat, corn, and soybeans (Table 3.1), which are also the most abundant crops in

Table 3.1. Most extensive crops in Kansas, 2012
(adapted from U.S. Department of Agriculture 2013).

Crop	Acreage (1,000 acres)	Production (1,000 units)
Wheat	9,100	382,200
Corn	3,950	379,200
Soy	3,810	83,820
All Hay	2,750	4,340
All Forage	2,750	4,545
Sorghum	2,100	81,900

Table 3.2. Kansas Study Site Planting Dates
(adapted from Shroyer et al. 1996).

Crop	Planting Date Range
Wheat	25 September to 20 October
Triticale	1 September to 25 September
Winter Barley	15 September to 10 October
Spring Barley	25 February to 15 March
Spring Wheat	25 February to 15 March
Spring Oats	25 February to 15 March
Corn	1 April to 10 May
Sorghum	15 May to 20 June
Soybeans	5 May to 10 June

Pellegrini, Argentina. Additionally, Kansas has been the focus of a number of previous studies into the use of MODIS time-series for crop classification (Wardlow and Egbert 2002, 2005; Wardlow, Egbert, and Kastens 2007; Wardlow and Egbert 2008), and has a very detailed and easily-accessible crop cover dataset in the form of the USDA CDL, making it a natural choice for a preliminary study area to test my method.

I have chosen a small 100 MODIS pixel by 100 MODIS pixel study area just northwest of Wichita, Kansas. The communities of Valley Center, Sedgwick, and Halstead run linearly from the southeast corner to the northwest corner of the study so (Figure 3.1). I tested and verified the classification method in this area (see Appendix C on page 91 for a full overview of the Kansas testing), and I extracted the crop reference signatures used for the Argentina classification from this area. The typical planting dates for a variety of crops in this region are shown in Table 3.2. I chose this specific study site because of the mix of land covers including, but not limited to, corn, soy, sorghum, winter wheat, winter wheat and soy double crop, urban development, grassland, and forest in the 2012 CDL reference (Figure 3.2).

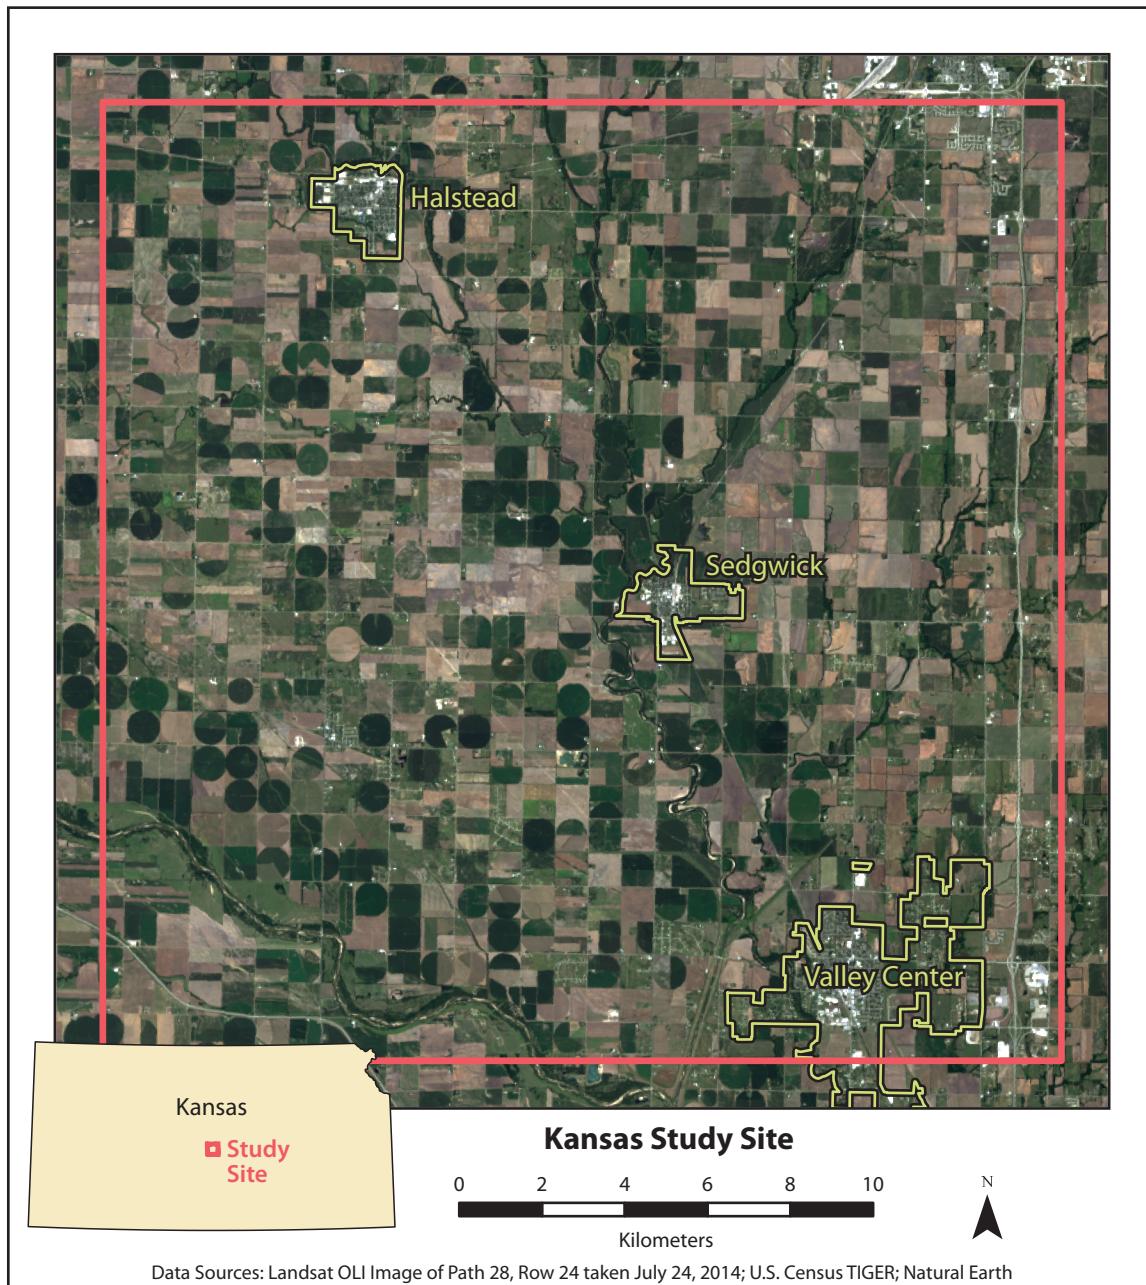

Figure 3.1. Kansas Study Site and the Communities of Halstead, Sedgwick, and Valley Center.

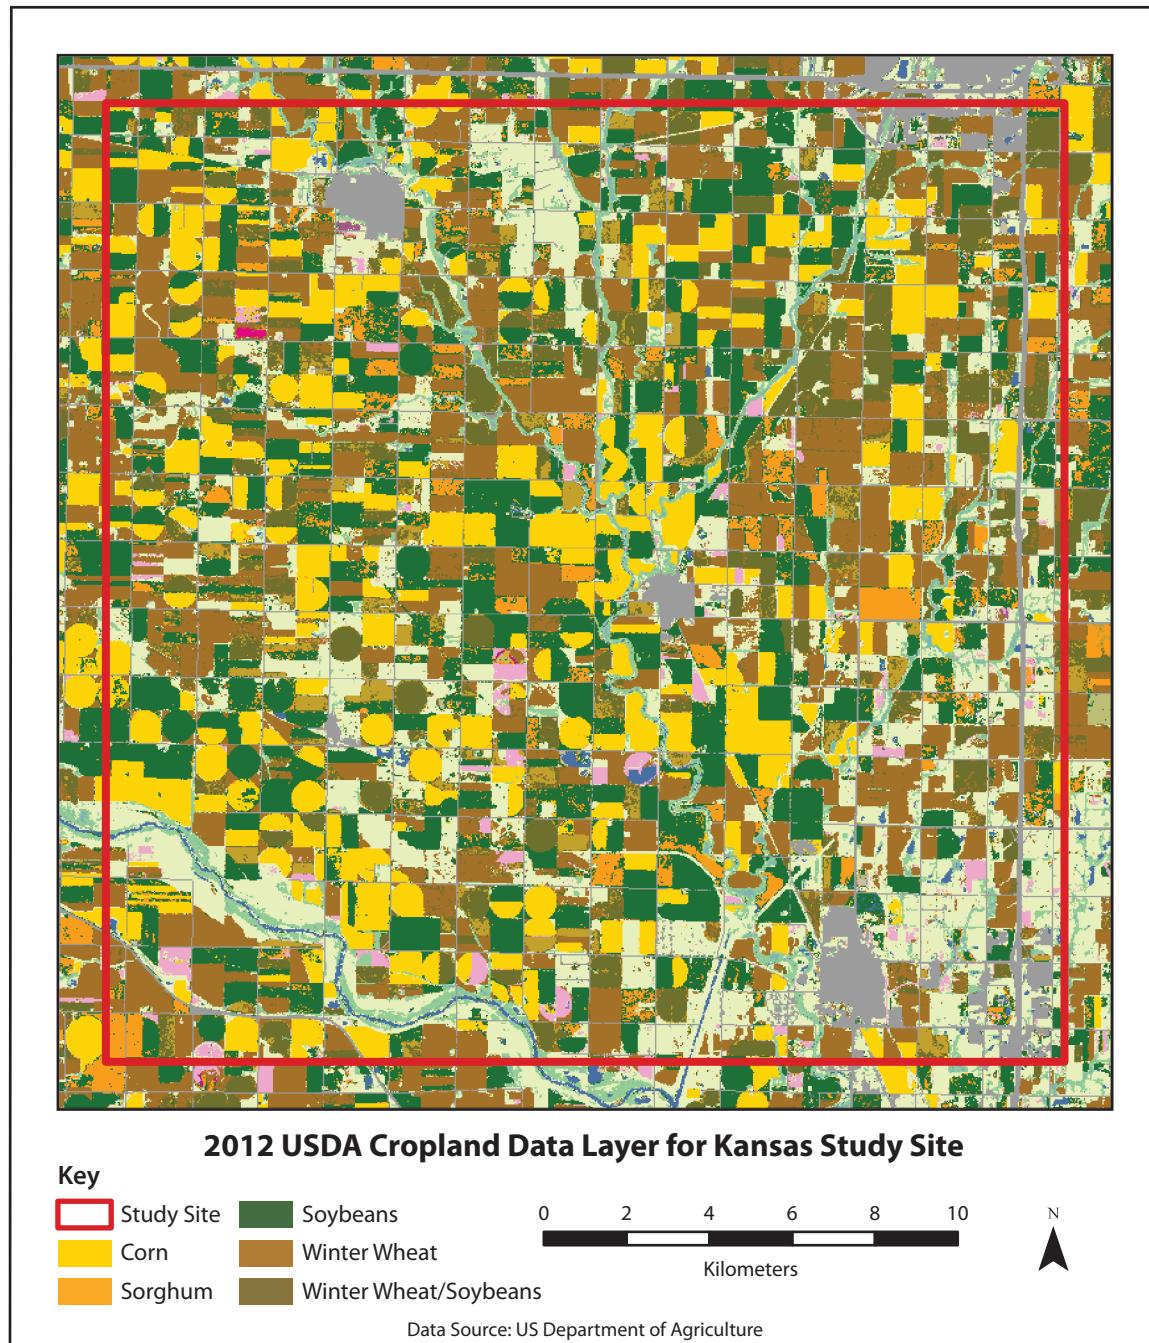

Figure 3.2. 2012 Kansas Study Site Crop Cover

Corn, soy, and winter wheat are the predominate crops in this area of Kansas, in line with the top three crops of the state as a whole. The sorghum sample size is comparatively small, but I found few areas with higher concentrations of sorghum.

3.2 Pellegrini, Santiago del Estero, Argentina

Santiago del Estero, a province in Northwest Argentina, has an area of 136,351 square kilometers, about the same as Arkansas, but a population of about 874,000 (INDEC 2010b). The entire province is classified within the *Parque Chaqueño* (Chaco forest), but, like the rest of Argentina forests, the forested area has declined rapidly over the past fifteen years. During the period 1998 to 2002, 306,055 hectares were deforested (Secretaría de Ambiente y Desarrollo Sustentable [Argentina] 2007). From 2006 through 2011, a further 701,030 hectares of forest were lost, 283,669 of which were after the enacting of the OTBN (Secretaría de Ambiente y Desarrollo Sustentable [Argentina] 2012). Over both of these time periods Santiago del Estero experienced the highest levels of deforestation in all of Argentina.

The Department of Pellegrini is an administrative area in the Northwest corner of the province of Santiago del Estero (Figure 3.3).¹ The department has an area of 6,944 square kilometers, a size slightly larger than the state of Delaware, and a 2010 population of only 20,514 (INDEC 2010a). The primary municipality of the department is Nueva Esperanza, with a population of about 4,500. Figure 3.4 shows the progression of deforestation in the department. Sometime between 1975 and 1993, an initial push for land began deforestation. The frontier nature of Pellegrini seemed to limit deforestation for some time. As can be seen from the satellite imagery, little changed between 1993 and 2001. And over the years 2001 to 2005, Volante et al. (2005) only 5,968 hectares were found to be deforested. However, a recent push for land has increased the rate of deforestation. From 2006 to 2011 the area deforested increased to 75,349 hectares, some 39,480 hectares cut after the enacting of the

OTBN, a rate much higher than previously witnessed (Secretaría de Ambiente y Desarrollo Sustentable [Argentina] 2012). Of the area cleared post-OTBN, 2,181 hectares were in red areas, the highest clearing of that designation in the nation. The vast majority of clearing, however, was 29,796 hectares in yellow areas. While Pellegrini's total deforestation during the period 2006 to 2011 was not the highest in Santiago del Estero, as both Moreno Department and Alberdi Department had higher total deforestation, as a percent of total land area Pellegrini's deforestation occurred at a greater rate: 10.85 percent of Pellegrini's land area was cleared versus 10.45 percent and 7.91 percent of Moreno and Alberdi, respectively.

Volante et al. (2005) found Pellegrini's primary summer crop over the years 2000 to 2005 to be soy, averaging about 40,000 hectares cultivated per year. Corn was the second most frequent crop, occupying about 7,500 hectares per year. *Poroto*, a generic term for many types of common beans, were the third most popular, averaging a total cultivation of about 2,500 hectares per year. The primary winter crop was wheat, though cultivation varied wildly from less than 10,000 hectares in 2002 to over 31,000 hectares in 2004.

Specific planting dates for Pellegrini are not available, but crop calendars for Argentina as a whole do provide generalized information (U.S. Foreign Agricultural Service Office of Global Analysis 2008; Sacks et al. 2010; Soybean And Corn Advisor 2013). Corn is typically planted mid-September through the end of November, and sorghum follows about twenty days later. Soybeans are planted in two groups: early and late. Early soy is often planted mid-November through the end of December, while late soy follows the harvesting of winter wheat, typically between the beginning of December through the middle of January. Compared to Table 3.2, these dates are approximately six months offset, congruent

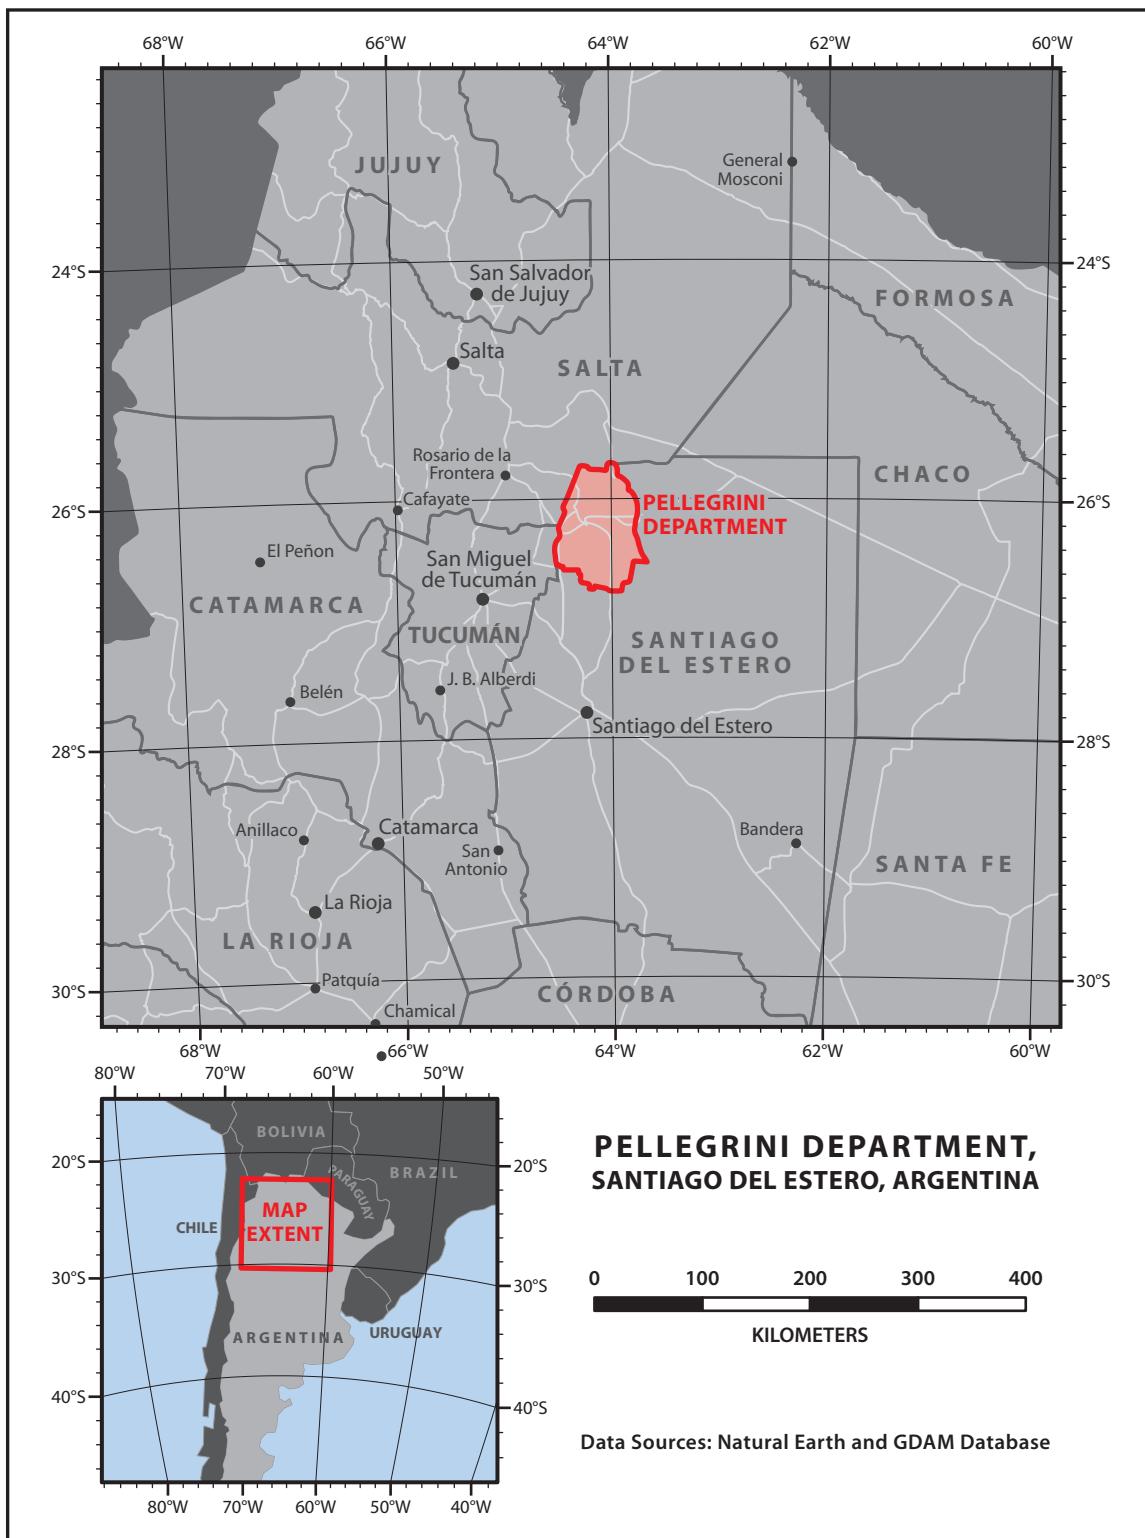

Figure 3.3. The Department of Pellegrini and the Greater Northwest of Argentina

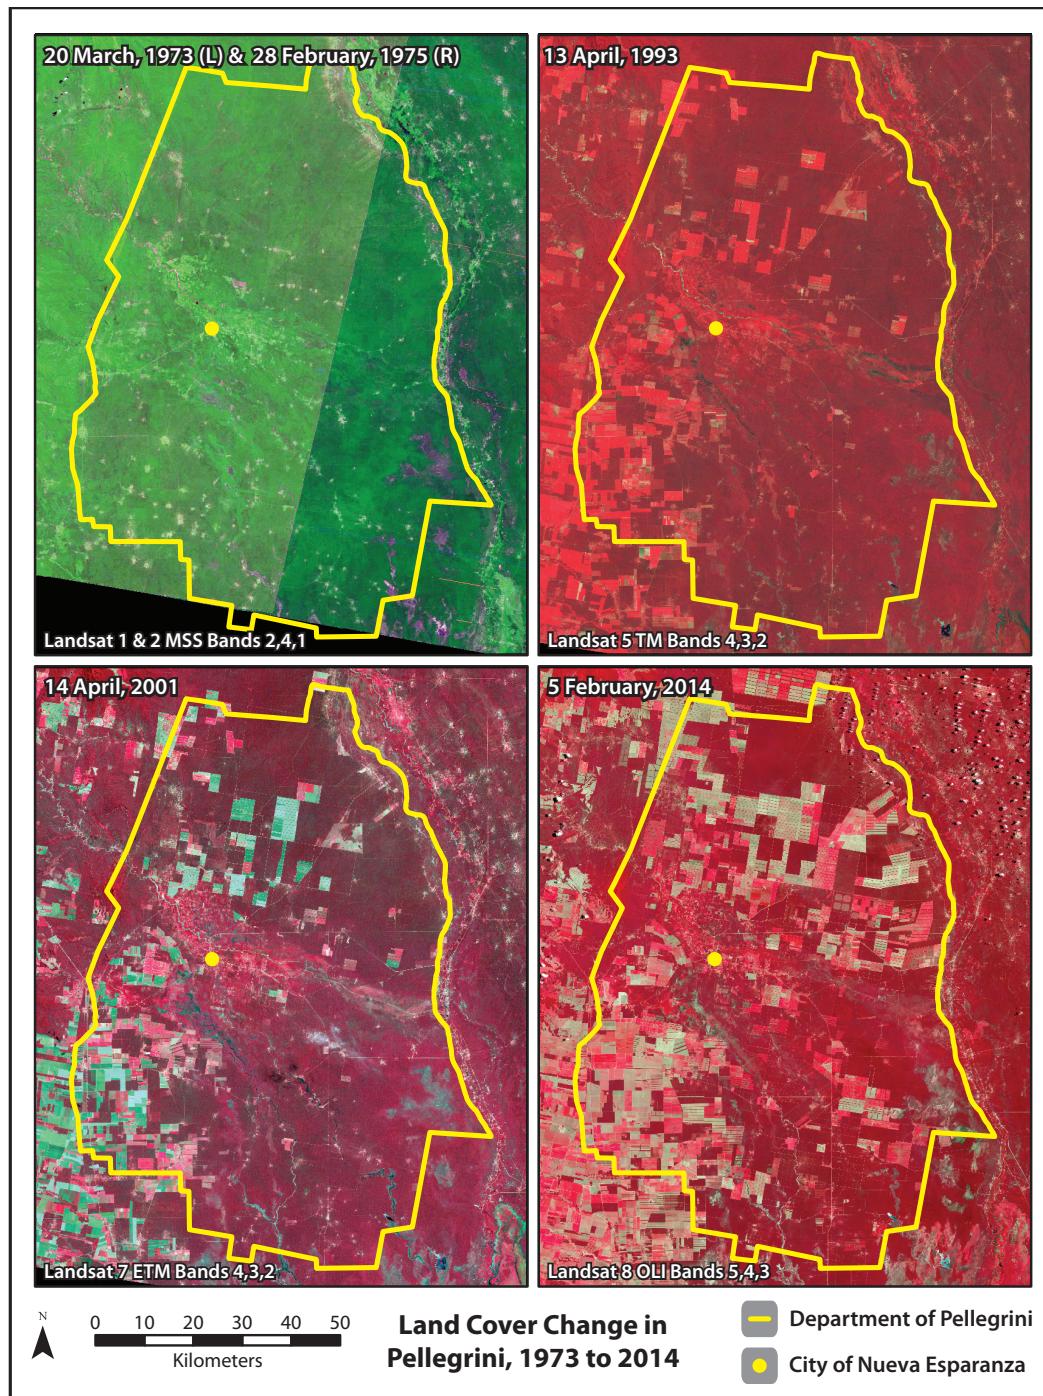

Figure 3.4. Land Cover Change in Pellegrini from 1973 to 2014

These images show the progression of deforestation in Pellegrini. The lack of deforestation in the 1973-1975 composite is striking. As early as 1993, deforestation is visible, primarily in the Southwest along the RN34 highway. Little changed between 1993 and 2001, but by 2014 much more deforestation is visible throughout the entire area.

with Argentina's opposing location in the Southern Hemisphere. However, the Argentina planting date ranges are noticeably longer than those in Kansas.

Notes

¹The Pellegrini boundary shapefile I obtained does not accurately reflect the bounds of the department on the ground. Particularly along the lengthy and straight northwestern edge, careful inspection reveals a lack of registration between the vector geometry and the obvious boundary visible in the background image. When investigating some of my sample points along the northern and southern edges, I got strange looks and comments about how this or that field was not within Pellegrini, my supposed study area. I want to acknowledge that I realize my study area is not actually the Department of Pellegrini proper, but an inaccurate representation as defined by a shapefile from the Internet. I use this inaccurate representation to ensure consistency, to allow repeatability, and to simplify spatial analysis.

Chapter 4

Data and Methods

4.1 Overview

This study has two purposes: (1) develop a set of tools to allow the classification of agricultural crops using a time series of imagery and known crop reference signatures, and (2) test the portability of said reference signatures. The known crop reference signatures were extracted from the Kansas study site, and their portability was tested by using them to classify the Argentina study site. The data used for this study consist of the following:

- 250-meter MODIS 16-day Composite Vegetation Index images
- 30-meter 2012 USDA Cropland Data Layer: agricultural land cover raster dataset
- 30-meter Landsat 8 Operational Land Imager satellite imagery
- Shapefile of the administrative boundary of the Department of Pellegrini

The MODIS VI composites were used as the source imagery for extracting phenological signatures and classifying the crop types. The CDL served as a ground truth for the Kansas study area. This dataset allowed identification of crop clusters when extracting signatures, and validation of the classification method. Landsat 8 OLI images of Pellegrini (path 230, row 78) from multiple dates were used during field data collection and subsequent digitizing.

All three of these data are publicly available from U.S. agencies. The Pellegrini boundary, used to define the Argentina study area, is from the GDAM Global Administrative Areas Dataset, version 1.0 (available at <http://www.gdam.org>).

Additionally, for the Pellegrini classification, I used a 2014 Pellegrini Land Cover vector dataset with crop identifications. I produced this dataset as a result of my fieldwork. As mentioned above, the data were digitized from Landsat 8 images, and land cover identifications were collected in the field.

An outline of the processing workflow is below:

1. Reproject the MODIS composite imagery
2. Assemble individual composite images into single time series images, one for Kansas and one for Argentina
3. Identify all the “pure” pixels—those containing a single land cover type (e.g. non-mixels)—in the Kansas TSI by overlaying the CDL with the MODIS pixel grid
4. Use the CDL to isolate the pure corn, soy, and sorghum pixels in the Kansas TSI
5. Identify the unique phenological groups in each set of isolated pixels using k-means clustering
6. Extract the pixel values for each unique phenological group from the time series image and find the mean value for each date to form the unique signatures for each crop
7. Fit the Kansas signatures to the Kansas TSI using the TSF method (see section 2.4)
8. Classify the Kansas RMSE rasters and assess the classification accuracy
9. Fit the Kansas signatures to the Argentina TSI
10. Classify the Argentina RMSE rasters and assess the accuracy

This chapter is a look at the methods and fieldwork used to create the validation land cover dataset of Pellegrini, and the data processing steps used to generate the study results.

Details about the specific tools in the classification toolset and the development process can be found in Appendix B. For a detailed explanation of all the testing proceeding this study, please see Appendix C. A thorough recounting of my field experience can be found in Appendix A.

4.2 Field Methods and Data Collection in Pellegrini

While ground truth data were easily available for the Kansas study site, getting a ground truth dataset for verification of the classification in Pellegrini was not so simple. Such a dataset did not exist, necessitating onsite data collection. I visited Argentina during the summer 2014 growing season to gather field observations of summer crop types and to talk to local farmers about typical agricultural practices, summer and winter crop varieties, and planting and harvesting dates.

To guide my ground truth collection, I generated 400 random points inside the Pellegrini shapefile boundary, and used a Landsat OLI image as a reference for land cover (image date 5 February 2014). Where a point fell within a mixel, I allowed it to be moved within a 3-by-3 pixel window centered on the point's original pixel, trying as much as possible to keep the point within a pixel belonging to the feature type on which it originally fell. In certain limited cases, if a point fell quite obviously within a field but the center pixel and eight surrounding pixels were mixels and/or were not within the field, I allowed the point to be moved to the closest full pixel of that same continuous field. Of the 400 points, I had to move 106 within the 3-by-3 window, and ten to a non-neighboring pixel within the same field.

From these adjusted points, I was able to establish 247 were forested using Landsat im-

agery. I did not need to visit these. For each of the remaining 153 I did need to visit, I created map sheets—one for every point, centered on the point—showing the point and satellite imagery at three different scales: (1) an overview at 1:60,000 scale with the 5 February 2014 Landsat OLI image; (2) a closer view at 1:30,000 scale, again with the Landsat OLI image, with an addition overlay of the MODIS pixel grid; and (3) a very large scale 1:4,500 scale view with older but higher resolution imagery from Digital Globe. I also created a 25-kilometer grid over Pellegrini, which I used to make eighteen smaller-scale “regional” maps at 1:150,000 scale to help identify neighboring points and plan routes. Lastly, I made an overview map of the entire department at 1:475,000 scale. I printed all of these maps and put them in a binder, so I could take notes and record the crop types in the field. I also planned to collect data about as many fields as I could, even those without sample points.

The primary means of gathering the crop identities to complete the ground truth was direct observation. When direct observation was not possible, I interviewed local farmers and land owners. In such cases, the interviewees were asked to identify their fields on the printed maps and describe their cultivars. Finally, if no knowledgeable local could be found, visual interpretation of the Landsat imagery was attempted using the appearance of already-identified fields as reference. If an identification was uncertain, the point was removed from the sample set. All the collected data were recorded directly on the sample point maps and later manually digitized.

Ancillary information about agricultural practices in the region was also collected whenever possible. It was a key goal to identify each crop’s date range for planting and harvesting in order to allow: (1) the proper selection of MODIS imagery dates, and, (2) appropriately

setting the $tshift$ bounds for Equation 2.5, enabling the temporal alignment of the Kansas reference signatures with the date range of the Pellegrini growing season.

4.3 Data Processing

4.3.1 Resampling the CDL

To use the CDL as a ground truth with the Kansas TSI, the 30-meter CDL pixels were resampled by majority to match the larger TSI pixels. This allowed a direct comparison between the crop values from the CDL and the pixel signatures in the TSI.

4.3.2 Building the TSIs

For this study, I chose to classify the 2012 Kansas summer growing season and the 2014¹ Argentina summer growing season. I assembled the MODIS 16-day composite VI images into multi-date time-series images (TSI) covering the growth cycle of the summer crops, where each band in a TSI is a 16-day composite VI and the bands are ordered consecutively (see section B.2 on page 82 for the description of the Build Multidate Image Tools). The Kansas summer TSI covered the date range DOY 97 through DOY 273, and was made with data from the Terra satellite (LPDAAC product MOD13Q1, tile h10v05). Prior to creating the TSIs, each of the 16-day composites was reprojected from the native MODIS sinusoidal reference system using LPDAAC's MODIS Reprojection Tool (LPDAAC 2011). I reprojected the Kansas data into the Albers Equal Area Conic projection for the contiguous U.S. using the 1983 North American Datum (WKID: 5070) to match the reference system

of the USDA CDL.

In Argentina, as it is in the Southern Hemisphere and the seasons are inverted to those of the Northern hemisphere, the growing season shifts, as must the date range for the VI time-series. The TSI for Pellegrini must begin at the end of the proceeding year to adequately capture the entirety of the summer phenologies. To accomplish this, the time-series image for summer 2014 began with the 16-day composite image from DOY 353 of 2013 (or DOY -13 with reference to 2014) and ended with the image from DOY 161 of 2014 (MODIS grid tile h12v11). This specific date range was chosen based on information provided by local farmers to ensure coverage of the earliest planting and latest harvesting dates, as well as manual inspection of pixel signatures throughout the study area. Persistent clouds necessitated using an image from the Aqua satellite of DOY 105 (LPDAAC product MYD13Q1) in place of DOY 113 from Terra. Due to no viable imagery from Aqua or Terra, DOY 129 was interpolated via a simple mean from the DOY 105 Aqua image and the DOY 145 Terra image. The Argentina composite images were reprojected with the UTM Zone 20S reference system (WKID: 32720).

4.3.3 Eliminating Mixels

After building the TSIs, the next processing step was to eliminate mixels from the Kansas TSI. Mixels, or pixels that contain more than one land cover type within the 250 by 250 meter cell area, have mixed temporal signatures, and cannot be clearly classified. To prevent errors, mixels had to be removed from the Kansas datasets (see section C.2 on page 98 for more information). Pure pixels, the non-mixels in an image, were isolated using ArcGIS

(ESRI 2012) by intersecting a vectorized version of the original 30-meter CDL ground truth with a vector grid of the TSI pixels. From the resulting geometry, all polygons with an area greater than 53,000 square meters (or 98 percent of a MODIS pixel) were selected as pure. I also manually selected two sorghum pixel features that were omitted due to intermixed soy pixels. I chose to add these pixels due to the low number of sorghum features retained, and that the intermixed soy appeared to be errors.

All of the other polygon features were discarded. The remaining polygon features were converted to point features based on their centroids, and these points were used to find the TSI pixel coordinates of the pure pixels in the subsequent processing steps, including extracting the reference signatures.

4.3.4 Extracting the Reference Temporal Signatures

As a reference library of temporal signatures does not yet exist, I had to extract my own signatures from the Kansas TSI. To do so, the pure TSI pixels of each key summer crop—corn, soy, and sorghum—as specified in the resampled CDL were isolated in separate rasters. Each of separated rasters was clustered into three clusters using the ENVI (Exelis Visual Information Solutions 2014a) k-means tool. K-means is an iterative unsupervised classification technique where data are clustered using the minimum distance to the nearest cluster centroid (Exelis Visual Information Solutions 2014b; Matteucci, n.d.). The centroids begin equally distributed throughout the data, but are recalculated on each iteration based on the shapes of the clusters in the previous iteration. The algorithm stops after the maximum number of iterations have been run, or when the cluster pixel counts change

less than a given percent threshold. I chose to use a 1.0 percent change threshold over 100 maximum iterations. The TSI pixels in each cluster were then sampled and averaged to find the three primary signatures for each crop² (see section B.3 on page 83 for information about the Extract Signatures Tool).

4.3.5 Fitting the Reference Signatures to the TSIs and Creating the RMSE Rasters

To find the degree of fit between reference signatures and unknown pixels, I used the TSF comparison method without the wavelet filtering. That is, a tool based on Equation 2.3 (page 15) was implemented using the programming language Python (Python Software Foundation 2014). Details of the tool can be found in section B.4 on page 84. The tool iterates through every pixel in a TSI, comparing each reference signature with the pixel values (i.e. MODIS NDVI values) and calculates the RMSE between the signature and the pixel values. An output raster is created for each crop type to record the RMSEs.

The reference signatures extracted from the Kansas TSI clusters were fit to the Kansas TSI and the output RMSE rasters were classified and verified. Then, the same Kansas signatures were fit to the Pellegrini TSI within the study area. The output RMSE rasters from each crop type were then classified. For both Kansas and Pellegrini, the bounds for the *xscale* and *yscale* parameters, which account for differences in growing season length and plant health, respectively, were 0.6 to 1.4. The *tshift* parameter, which temporally aligns the reference signature to a pixel's values, was bounded to -10 to +10 days for the Kansas fit processing. The bounds for the Pellegrini fit processing were 120 to 140 days (still ± 10 days, but shifted 130 days).³

4.3.6 Classifying the RMSE Rasters

The classification process is complex; section B.5 on page 88 contains a full discussion of the process, so I will refrain from a lengthy description here.

Classifying the RMSE rasters first requires thresholding the RMSE values in each raster, then finding the lowest RMSE value for each pixel. The crop type of the thresholded RMSE raster that has the lowest RMSE value—that is, the crop type of the signature that matches the pixel values the best—is assigned to the pixel. The thresholding prevents pixels with poor RMSE values from being classified as a crop. If a pixel has no remaining RMSE values after thresholding, it is classified as “other.” Currently, appropriate RMSE threshold values are not well understood, so to find the best classification, the classification tool must brute-force through many combinations of RMSE thresholds within a user-specified range, classifying the RMSE rasters, and calculating the accuracy of each threshold combination in comparison with the ground truth dataset. A raster of the classification with the best accuracy is retained.

For the Kansas classification, it was easy to try iterating through different RMSE threshold ranges. However, the Argentina classification was not as straightforward. As the tool must brute-force through every RMSE threshold combination, the time required to find the best threshold in a range is exponential, given by the number of threshold steps to the power of the number of images, times the number of seconds for each iteration. The Kansas classification took under 0.3 seconds per iteration; classifying the larger area of Pellegrini took substantially more time, somewhere between three and four seconds per iteration. The

increased processing time ruled out using more than two or three threshold steps. Consequently, in the case of the Argentina classification, it was much more efficient to iterate through a range of RMSE threshold values using a single threshold value across all the RMSE rasters, then manually refine each raster's threshold value until finding the optimum combination.

Notes

¹To clarify, I have chosen to refer to the summer growing season by the harvesting year, given that the Argentine summer technically ranges from 21 December to 20 March. This is the same date range as the Northern Hemisphere's winter season, which is typically referred to by the year in which it ends, e.g. winter 2014. I find other references to the growing seasons in Argentina to be somewhat confusing. Often, a year range is used, such as 2013-2014, to denote that the grown season actually begins in 2013. Sometimes, as planting dates in Argentina as a whole are primarily September through December, the proceeding year is used to refer to the entire growing season, which I find especially misleading.

²Given the existing literature about phenological classification, I do not believe crops have multiple signatures. I believe every crop has a theoretical ideal signature, which can be made to fit any actual signature using the *xscale*, *yscale*, and *tshift* transformations in Equation 2.5, barring any unusual effects of weather or other forces impacting crop development (a mid-season drought, for example, may cause a crop signature with double peaks due to the partial dying off and regeneration of the plants). However, given my choice of the CDL as my source of ground truth, I have had to make the assumption that it is highly accurate, despite any evidence to the contrary (see my discussion of the CDL beginning in section C.3). Therefore, I use the clustering to derive the signatures that will create a classification most comparable to the CDL.

³I have not formally tested other bounds. See section D.3 on page 133.

Chapter 5

Results

5.1 Ground Truth and Agricultural Practices in Pellegrini

I travelled to Pellegrini 12 March through 3 April 2014 during the summer growing season to collect crop data. Using field observation, interviews, and satellite image interpretation, I gathered identifications for 378 of 400 sample points randomly distributed throughout the department, as well as many additional fields I also came across. Areas of homogeneous land cover were digitized from Landsat imagery, and the collected data was used to classify the digitized polygons, where applicable (Figure 5.1). Of my 400 sample points, I was able to visually classify 247 of the points as forested from Landsat OLI imagery before leaving for Argentina. Of the remaining 153, I identified 106 as actively-cultivated agriculture: thirty six points as corn, twenty four points as soy, two points as sorghum, seven points as poroto, and thirty seven points as pasture. Twenty two points were identified as “other,” representing all non-forest, non-agricultural, and/or mixed-use land cover classes. Another three points, based on the literal descriptions communicated to me by land managers, were identified as “nothing.” I am unsure if these fields were simply left fallow or are something

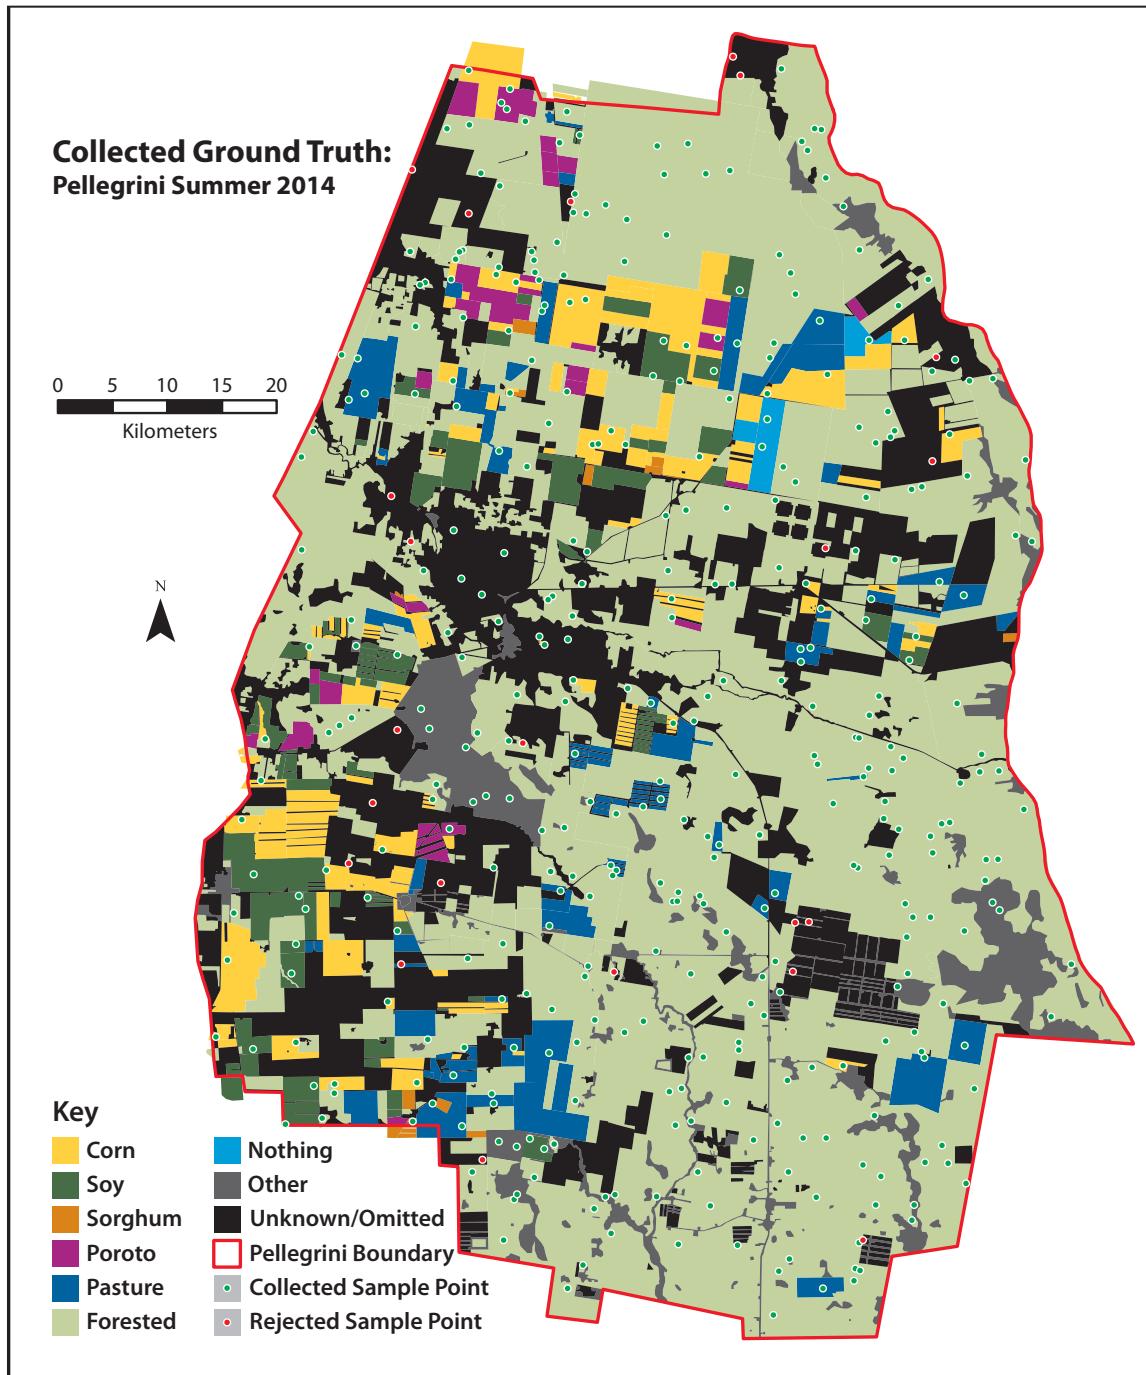

Figure 5.1. Pellegrini Summer 2014 Collected and Digitized Ground Truth Dataset

Table 5.1. Summer 2014 Pellegrini Land Cover Classes, From Ground Truth
By Area, with Sample Point Counts

Cover Type	Hectares	Sample Points
Forested	389,541	247
Other	42,229	22
Corn	41,488	36
Pasture	35,057	37
Soy	27,498	24
Poroto	9,539	7
Nothing	3,057	3
Sorghum	1,646	2
Unknown	92,248	17
Omitted	52,052	5
Total	694,346	400

else, but they are not under active cultivation. Twenty two points could not be verified due to inaccessibility, uncertainty, or falling on a mixed-use area, and were removed from the final set of sample points used for the accuracy assessment.

I tried to get direct observations of all crop sample points to accurately record the crop types. However, this strategy proved to be difficult in many cases; I was able to visit only forty seven of the crop points. Often, fields were inaccessible due to road conditions or locked gated. Forty five crop observations came from interviews with farmers and land owners. In a few cases I was able to meet with agricultural engineers who were even able to provide me with maps of the fields they managed (see Figure 5.2). The last fourteen crop point identifications were interpreted from Landsat imagery.

The total area of each of land cover class is shown in Table 5.1. Compared to the 2000 through 2005 crop areas from Volante et al. (2005), corn seems to have expanded significantly in the area, while soy has retreated, despite the impression of the contrary in

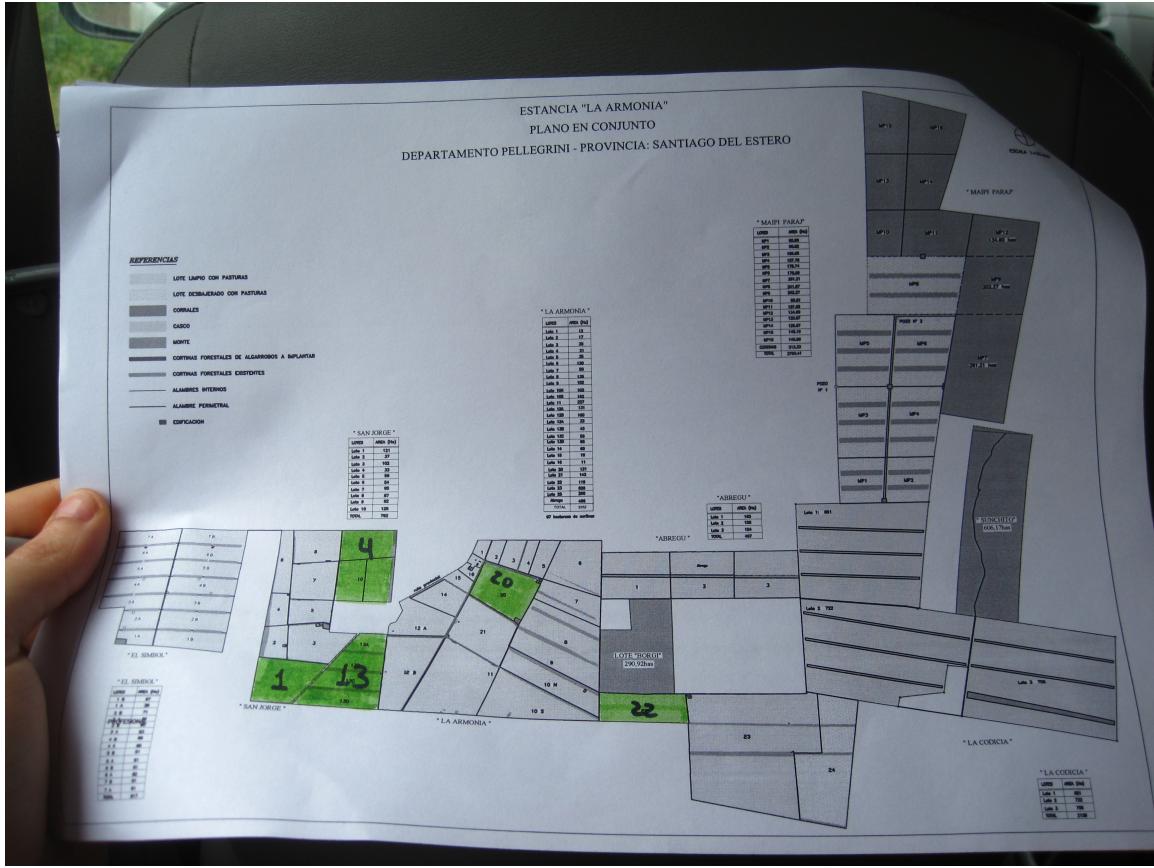

Figure 5.2. Map of *Estancia La Armonia*, a Large Farm

This map is exemplary of those used by the larger farming operations to plan their land use. This farm, *Estancia La Armonia*, primarily raises cattle, so most all of the fields shown are pasture areas. The fields shown highlighted in green are sorghum, which I was told is used as part of the feed mixture in a small cattle feedlot operation.

the country as a whole. I gathered from talks with farmers that the decline of soy may be due to increased expenses in the region due to pests, fungus, poor soil, and transportation. Sorghum, a hectare count of which Volante et al. omitted for Pellegrini, does not occupy much land relative to the other crops, and, across Argentina as a whole, experienced a significant decline in production from 1970 to 2003 (Paruelo, Guerschman, and Verón 2005). However, the 1,646 hectares I observed may indicate a reversal of sorghum's popularity due to increasing demand as cattle feed in feedlots, and could likely be a bigger piece of the

Table 5.2. Typical Planting Dates for Summer Crops, Pellegrini, Argentina

Crop	Ideal Planting Range	Latest Planting Date	Harvesting Begins
Soy	15 December to 15 January	End of February	1 May
Corn	15 January to 15 February	End of February	1 June
Sorghum	15 January to 15 February	End of February	1 June
Poroto	15 January to 20 February	Early March	10 May

Pellegrini agricultural pie in coming years.

In conferring with local farmers and land owners, I found the typical planting and harvesting dates for the major summer crops of soy, corn, sorghum, and poroto, shown in Table 5.2. The dates I collected did not match those I found published for the country as a whole (see section 3.2, page 22). In fact, based on my data, soy is most frequently planted before corn, in contrast to Kansas and the rest of Argentina (see Table 3.2 on page 19 for Kansas dates). I was also told that the winter growing season is separate from the summer growing season. Unlike Kansas, where the beginning of the summer crops (namely corn's early development) overlaps with the end of winter wheat growth, the harvesting of Pellegrini's winter crops is typically completed before summer planting begins. Thus, where double cropping is limited in Kansas to a winter crop and a late-developing summer crop (overwhelmingly a winter wheat and soy or winter wheat and sorghum combination), any winter crop can be paired with any summer crop in Pellegrini.

5.2 Elimination of Mixels

I found 1,359 pure pixels in the 100 pixel by 100 pixel Kansas study area. The low percentage of pure pixels in the study area is due to the large pixel size relative to the fields,

Table 5.3. Summer 2012 Kansas TSI Mixel and Pure Pixel Counts

	Count	Percent of Total
Total Pixels	10,000	100.00
Pure Pixels	1,359	13.59
<i>Corn</i>	414	4.14
<i>Soy</i>	354	3.54
<i>Sorghum</i>	16	0.16
<i>All Others</i>	575	5.75
Mixels	8,641	86.41

as well as a few irregular features cutting across the pixel grid. The distribution of pure pixels across the land classes is shown in Table 5.3.

5.3 Extracted Reference Signatures

Before extracting the reference signatures for each summer crop, the pixels for each crop had to be clustered. Figure 5.3 shows the spatial distribution of the three clusters for each crop. Given the small number of pixels, the k-means algorithm only found a single cluster for sorghum.

The temporal signatures of each of the clusters are plotted in Figure 5.4. Each of the crops have a somewhat similar appearance to one another, but each can be differentiated: corn peaks earlier in the year than soy or sorghum, soy has a rounder peak than corn, while sorghum has lower VI values and a slightly later growing season than soy.

5.4 Fitting and Classifying the TSIs

Fitting the seven crop reference signatures—three corn, three soy, and one sorghum—to the TSIs produced seven RMSE rasters for each TSI. The minimum RMSE values were

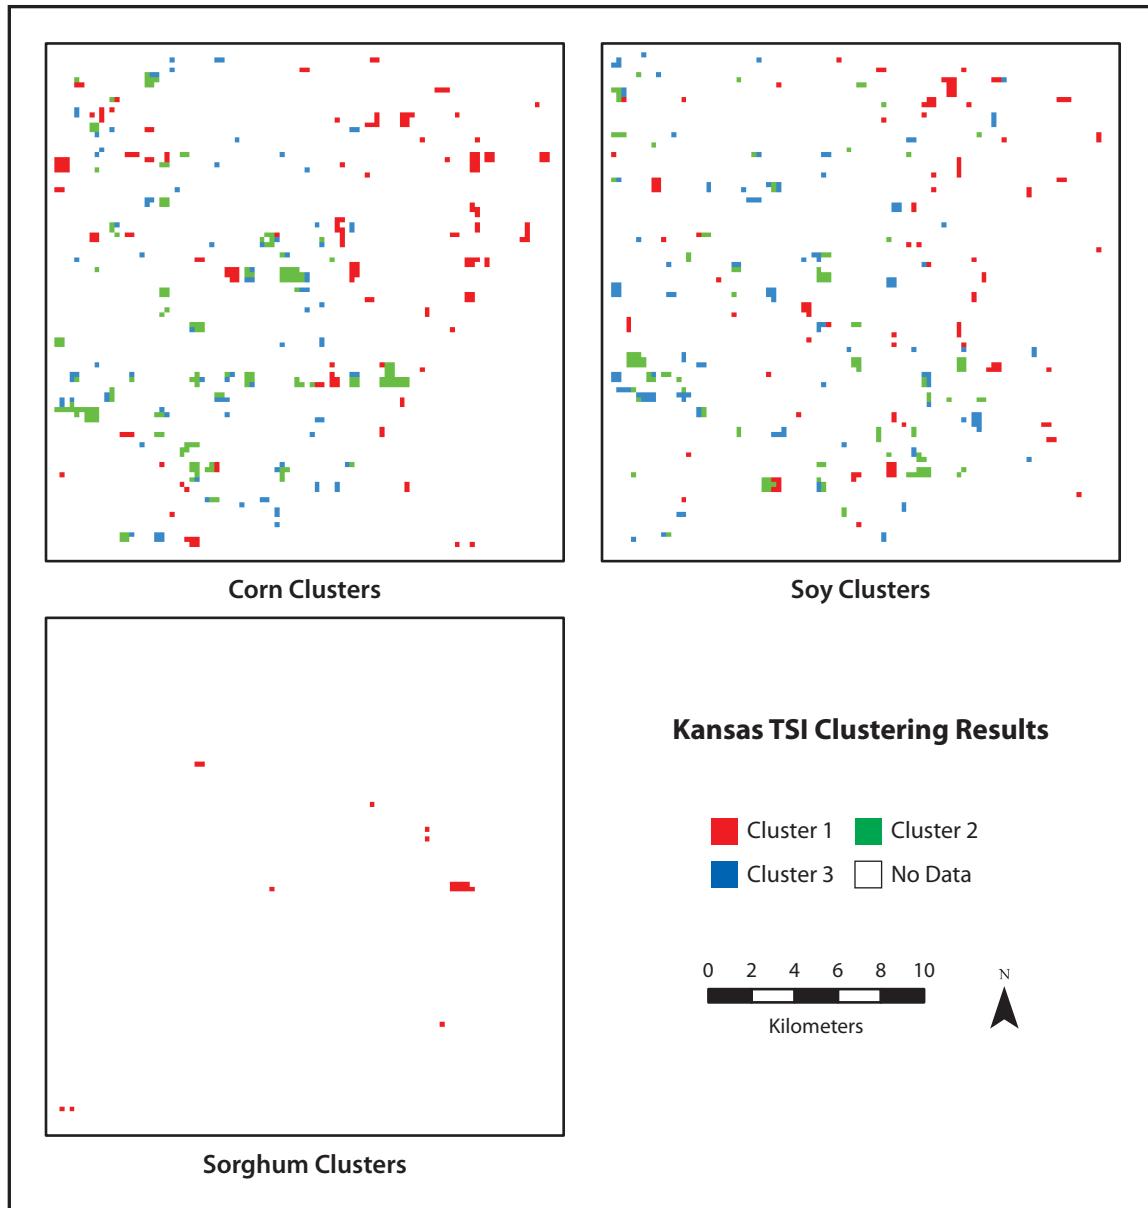

Figure 5.3. Clustering the Kansas TSI Image into Three Clusters for Each Crop

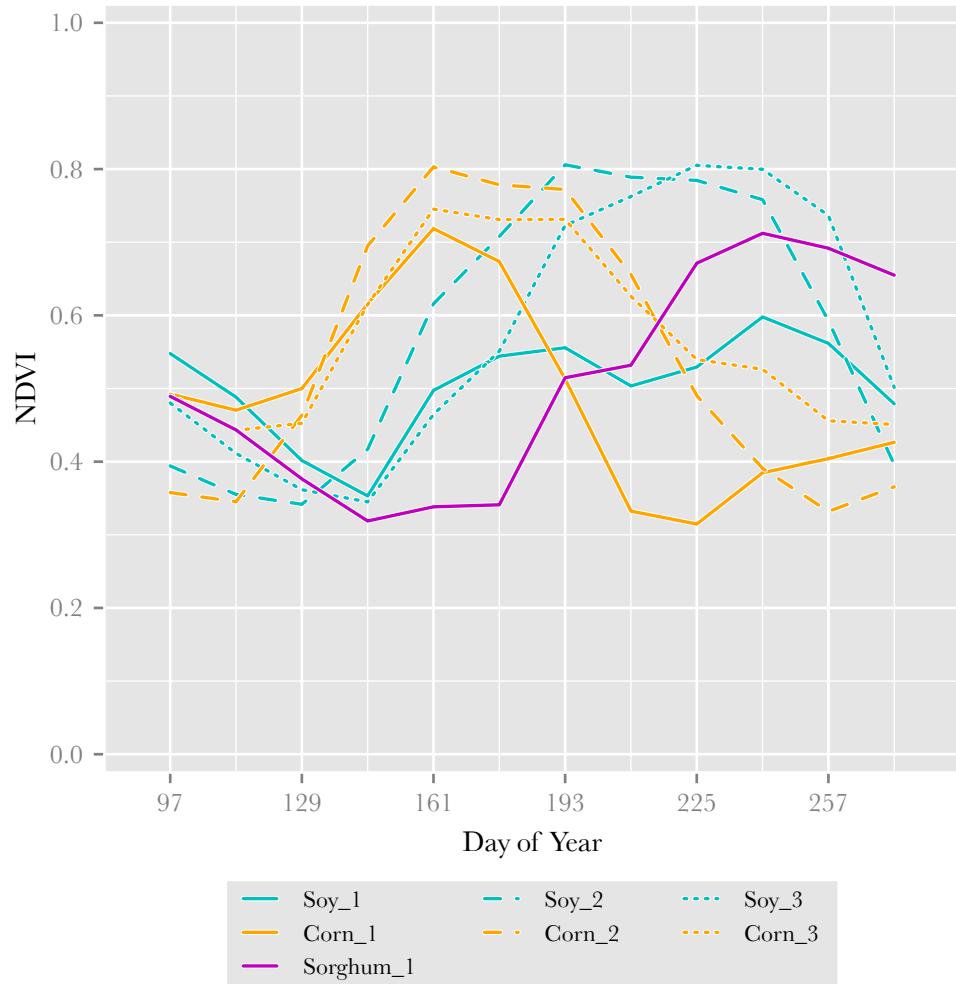

Figure 5.4. Crop Signatures Extracted from the Kansas TSI Crop Clusters

Shown are the seven crop signatures extracted from the Kansas study site's TSI using the k-means clusters. Notice how all three corn signatures occur earlier in the year than the soy or sorghum signatures, but otherwise look similar to the soy signatures. The temporal separation assists with classification. The Soy_1 signature is strange in appearance; it does not look anything like a typical soy signature. Over this date range, the Sorghum_1 signature loses much of its downslope at the end of its growth.

Table 5.4. Summer 2012 Kansas Study Site Classification Accuracy

		Reference Data					
		Corn	Soy	Sorghum	Other	Total	User Acc.
Classified	Corn	369	65	5	17	456	80.92%
	Soy	32	273	10	47	362	75.41%
	Sorghum	0	0	2	6	8	25.00%
	Other	13	16	1	503	533	94.37%
	Total	414	354	18	573	1359	
	Producer Acc.	89.13%	77.12%	11.11%	87.78%		
							Overall Accuracy: 84.40%
							Kappa: 0.76

typically in the range of 175 to 250, while the maximum RMSE values were often around 3000.¹

The Kansas classification achieved an overall accuracy of 84.4 percent, a map of which is shown in Figure 5.5; the confusion matrix is Table 5.4. This classification was generated by iterating over the range of RMSE thresholds from 450 to 1150 by steps of 150. The best RMSE threshold combination from that process was then manually adjusted by steps of 50 for each RMSE raster until the maximum accuracy classification was found using the RMSE thresholds in Table 5.5.

The Argentina classification had a top overall accuracy of 87.8 percent (Table 5.6). Look-

Table 5.5. Kansas Best Classification RMSE Thresholds

Signature	Threshold Value
Corn_1	1,000
Corn_2	750
Corn_3	500
Soy_1	750
Soy_2	1,300
Soy_3	500
Sorghum	450

ing more closely at the results, the accuracy seems to be skewed upward by the high number of non-summer-crop sample points, which were correctly classified as “other.” Within the summer crop sample points, the accuracy is much lower; only one of the twenty three soy points and zero of the two sorghum points were correctly classified. Corn fared a bit better, but was still underwhelming, as only 68.6 percent of the corn points were classified correctly. The RMSE thresholds used for this classification, in Table 5.7, show that the Corn_2 and Soy_3 signatures contributed to the classification most heavily, the Corn_1 and Soy_2 signatures contributed only a little, and the Corn_3, Soy_1, and the Sorghum_1 signatures did not contribute at all (hence the zero points of sorghum classified).

Table 5.7. Pellegrini Best Classification RMSE Thresholds

Signature	Threshold Value
Corn_1	550
Corn_2	850
Corn_3	0
Soy_1	0
Soy_2	600
Soy_3	950
Sorghum_1	0

A map of the classification, shown in Figure 5.6, illustrates how well the classification stayed within summer crop fields, and did not classify much beyond. However, almost all of the summer crop fields are classified as corn, reflecting the low summer crop accuracies shown in Table 5.6.

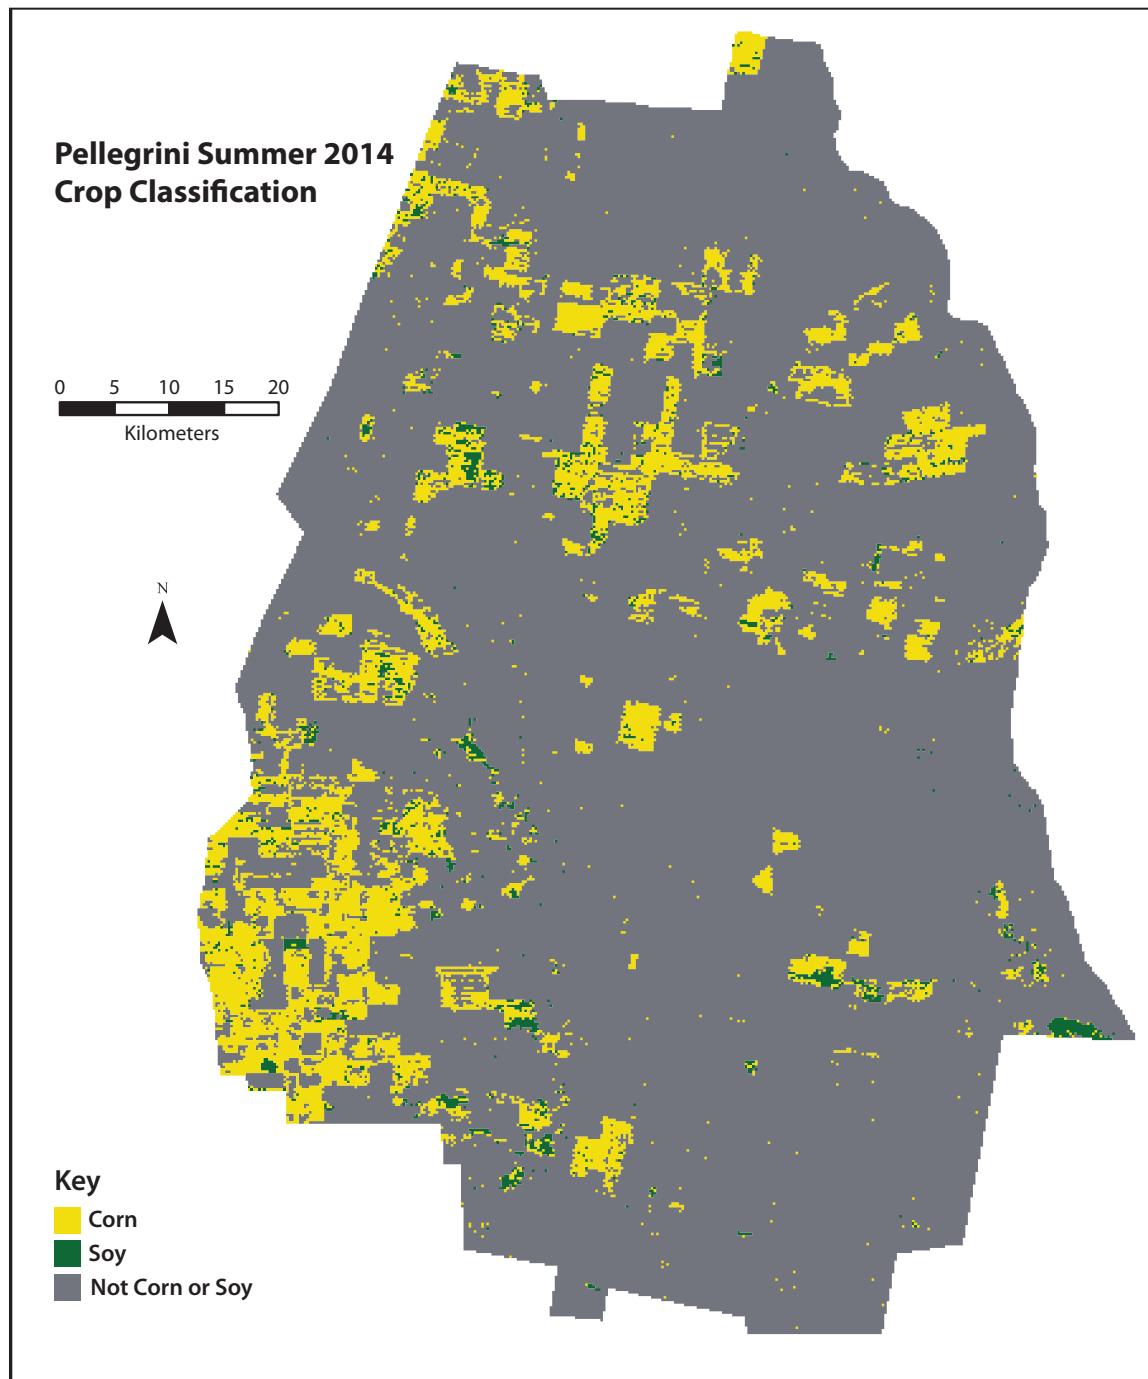

Figure 5.6

Notes

¹NDVI and EVI range between -0.2 and 1.0, so the RMSE values should be 0.0175 or 0.3000. However, the MODIS VIs are distributed as 16-bit signed integer rasters; to allow the VI values to be recorded with such a format, they are multiplied by 10,000, hence the values shown here. I chose not to convert the measurements back to the proper decimal values to simplify processing, though the tools I developed should work either way. Users must take the responsibility be aware of the significance of the RMSE values and understand what values to expect based on their input data.

Chapter 6

Discussion

6.1 Examining the Kansas Signatures

The Kansas signatures extracted from the k-means clusters (Figure 5.4) were not as variable as I was expecting. Based on some initial testing results, presented in section C.3 beginning on page 112, I expected to find some strange looking cluster signatures. Aside from the Soy_1 signature, and perhaps the Corn_1 signature to some degree, the cluster signatures were fairly typical in appearance. The Sorghum_1 signature appears more or less as expected over the TSI's date range, but does seem to be missing the late-season downslope.

Using the k-means algorithm to cluster each crop's pixels might not have adequately captured the variability in the crop signatures as labeled by the CDL to allow the fit algorithm to match the CDL classification. That is, perhaps k-means separates pixels that would have similar RMSE values when fit with the same crop reference signature. Future research might want to consider clustering based on the RMSE value of each pixel to the others; pixels with low RMSE values when compared to one another would be grouped

together, as they likely to be transformations of the same base temporal signature. Pixels with considerably different RMSE values would suggest different base temporal signatures.

Despite the fact the k-means might not capture similarity in the same way as the fit algorithm, it is worth noting that the k-means clusters do not divide any fields: each pixel in a field is assigned the same cluster (Figure 5.3). This result shows that each pixel in a field of multiple pixels typically has a similar signature to all the others in the field, at least using k-means as a measure of similarity. This result is further confirmation of the hypothesis that each pixel of a crop that grew under the same conditions, such as a field, should have the same development and therefore same temporal signature.

6.2 Breakdown of the Kansas Classification

The initial verification of the Kansas reference signatures, done by classifying the TSI of the Kansas study area, demonstrated the method performs well when used to match the original source data (Table 5.4). The 84.4 percent overall accuracy and kappa value of 0.76 are well within the range considered acceptable, especially given the CDL's published accuracy of 88.4 percent (to which this classification is compared).

Some confusion between corn and soy, as well as soy and “other,” pulled down the overall accuracy, as well as the producer and user accuracies of each of those classes. The similarities between the corn and soy signatures may cause late corn and early soy to be confused if the range of the offset of the beginning day of the reference signature, *tshift*, allows overlap between the two. I believe much of the soy and “other” confusion was due to the Soy_1 reference signature (Figure 5.4). Examining the CDL classes of the best fit pixels

in the RMSE raster showed a number of grassland pixels were well fit by that particular signature. However, omitting that particular signature seemed to allow one of the corn signatures to take many of the soy pixels, which I find strange due to the peculiar shape of the Soy_1 signature. In fact, the signature does not match the traditional soy signature, and makes me question the validity of the CDL in this case (also see section C.3 for more CDL problems, and Appendix E for notes about the CDL).

Classifying sorghum did not seem to be very effective; only two of the 18 sorghum pixels were accurately identified. The sorghum RMSE raster had the lowest threshold value at 450, but increasing the threshold only caused greater class confusion. Omitting the signature entirely had a slight negative effect on the overall accuracy, as the “other” pixels it misclassifies would otherwise be misclassified by corn and soy. It is possible that I should have added another 16-day composite to the TSI to capture the tail-end of the sorghum signature, though I believe doing so would have caused more harm as winter crop plantings would begin to interfere with summer crop signatures (see the “end-of-year bump” discussion in section C.4). Moreover, the similarities between sorghum and soy signatures might cause confusion if the sorghum threshold were to be raised. However, due to the low number of sorghum pixels, the validity of any conclusions about classifying this particular crop is questionable. A larger sample size and more testing are required.

6.3 The Pellegrini Classification and Class Confusion

As shown in Figure 5.6, classifying the Argentina TSI with the reference signatures from the k-means clustering of the Kansas TSI was able to effectively separate areas of the summer

crops corn, soy, sorghum, and poroto from most other land cover classes, but classified those summer crop pixels predominately as as corn. While Table 5.6 reflects this class confusion in the producer and user accuracies, the low sample count for corn, soy, and sorghum compared to all the other land covers deceptively skews the overall accuracy higher. Table 6.1 is the confusion matrix for the same classification, but compared to the entire ground truth dataset, encompassing some 85,821 pixels, instead of the rather limited 378 random sample points. While the overall accuracy actually improves slightly with this new reference dataset, it must be noted that neither of these accuracy assessments is able to account for errors resulting from mixels. However, the increased number of samples better demonstrates the significant corn-soy confusion. For instance, of the 6,621 pixels classified as corn, 2,076 are soy. Errors of omission are also more prominent: 2,234 of the 5,706 corn pixels were left as “other.” A similar proportion of soy pixels were also classified “other.” Increasing the RMSE thresholds on the RMSE rasters to decrease these omissions only increased the errors of commission, confusing “other” pixels for crops. The low kappa statistic of both accuracy assessments, 0.54 and 0.51 respectively, is reflective of the poor accuracies within the summer crops.

Considering that the “other” pixels contain a number of different classes, I found the frequency of corn and soy classifications within each of the “other” land cover classes. The results of this analysis (Table 6.2) show that the main sources of confusion were, from greatest to least, the true “other land cover” class, pasture, and poroto. However, when finding the percent of the land cover class pixels that were confused, poroto leads with over 26 percent of its pixels confused for either corn or soy. This confusion, and the confusion of some pasture

Table 6.1. Summer 2014 Pellegrini Best Classification Accuracy Checked Against All Pure Pixels

		Reference Data					
		Corn	Soy	Sorghum	Other	Total	User Acc.
Classified	Corn	3283	2076	61	1201	6621	49.58%
	Soy	189	313	36	458	996	31.43%
	Sorghum	0	0	0	0	0	0.00%
	Other	2234	1523	60	74387	78204	95.12%
	Total	5706	3912	157	76046	85821	
	Producer Acc.	57.54%	8.00%	0.00%	97.82%		
							Overall Accuracy: 90.87%
							Kappa: 0.51

areas as well, does make some sense, as these land covers, soy, and corn are all planted in spring and reach peak maturation during the summer months. Depending on the type of pasture, it may or may not grow back after cutting; if it does not, the temporal signature may bear some resemblance to corn or soy.¹

From their appearance in Landsat imagery, the main locations where the other class was confused for corn and soy seem to be bare earth, possibly due to high soil salinity. The areas have low-to-moderate reflectivity in the visual bands, high reflectivity in the mid-infrared, and low reflectivity in the near-infrared, and do not exhibit much change over time. However, the plots of a random sampling of pixels from the TSI show temporal signatures like

Table 6.2. Pellegrini Corn and Soy Confusion with “Other” Land Cover Classes

Land Cover	Total Pixels	Pixels Confused as Corn	Percent of Total	Pixels Confused as Soy	Percent of Total
Forested	63,978	194	0.30	26	0.04
Other	5,393	306	5.67	322	5.97
Pasture	5,252	396	7.54	50	0.95
Poroto	1,369	303	22.13	59	4.31
Nothing	485	2	0.41	1	0.21

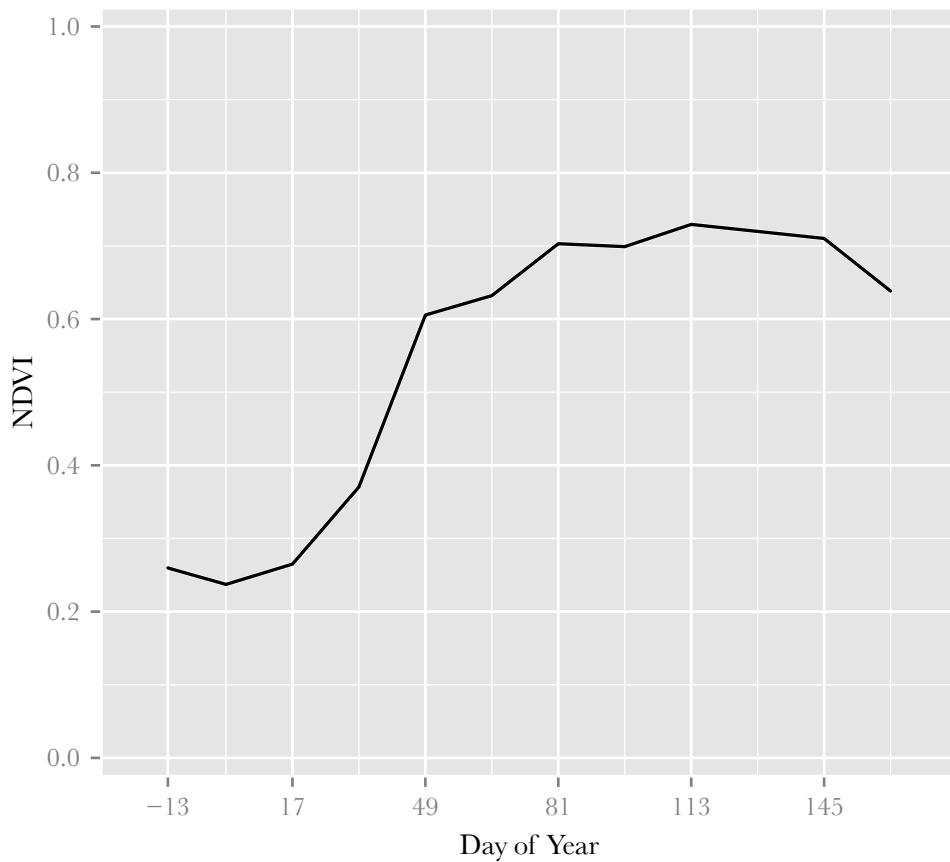

Figure 6.1. Signature of an Unknown Pixel Confused for Corn and Soy in Pellegrini

that in Figure 6.1. I am currently unable to explain what is in these areas or why they are confused for corn and soy. I believe there may be some sort of summer grass cover or other seasonal vegetation, but I cannot understand the lack of near-infrared reflectance as observed in Landsat images from multiple dates throughout the summer.

6.4 Clustering Pellegrini

To further examine the class confusion in Pellegrini, I used the same k-means clustering as in Kansas to identify the three main signatures for each of the eight land cover classes

in the ground truth dataset. The extracted corn, soy, and sorghum signatures are shown in Figure 6.2, while the poroto and pasture signatures are in Figure 6.3.

The cause of the corn-soy confusion is immediately visible: both crops peak around the same date. I did not expect this result, as the typical planting dates I collected suggest soy should peak earlier than corn.² However, I also gathered that precipitation was the limiting factor in planting (confirmed by (Sacks et al. 2010)), and often farmers will wait until a certain amount of rain has fallen before planting. In fact, I was told the rains this year were quite late, and on multiple occasions farmers told me they had planted a field late due to lack of rain. While I must admit I am not a farmer and do not know this for certain, the reason for waiting did not seem to be out of concern for plant health, in that too early of planting would negatively impact the crop's health, but seemed to be primarily economic: farmers do not want to pay to plant crops that will not grow if the rains never come.

The forest, nothing, and other signatures are in Figure 6.4.

I also observed fields of corn, soy, sorghum, and poroto in many different states of development, from the early, barely-germinated stage to the late, fruit-bearing stage. To me, the broad range of development is likely because water is the only limiting factor defining the typical planting dates. That is, the threat of changing temperatures does not affect planting decisions like in Kansas, and farmers have much more flexibility (this flexibility has been observed in other regions per Sacks et al. (2010)). Additionally, early and late planted crops should mature about the same time, due to their development being limited by water. My method should be able to accommodate the range of planting and maturation dates by adjusting the bounds on the *tshift* parameter, allowing the reference signatures more freedom

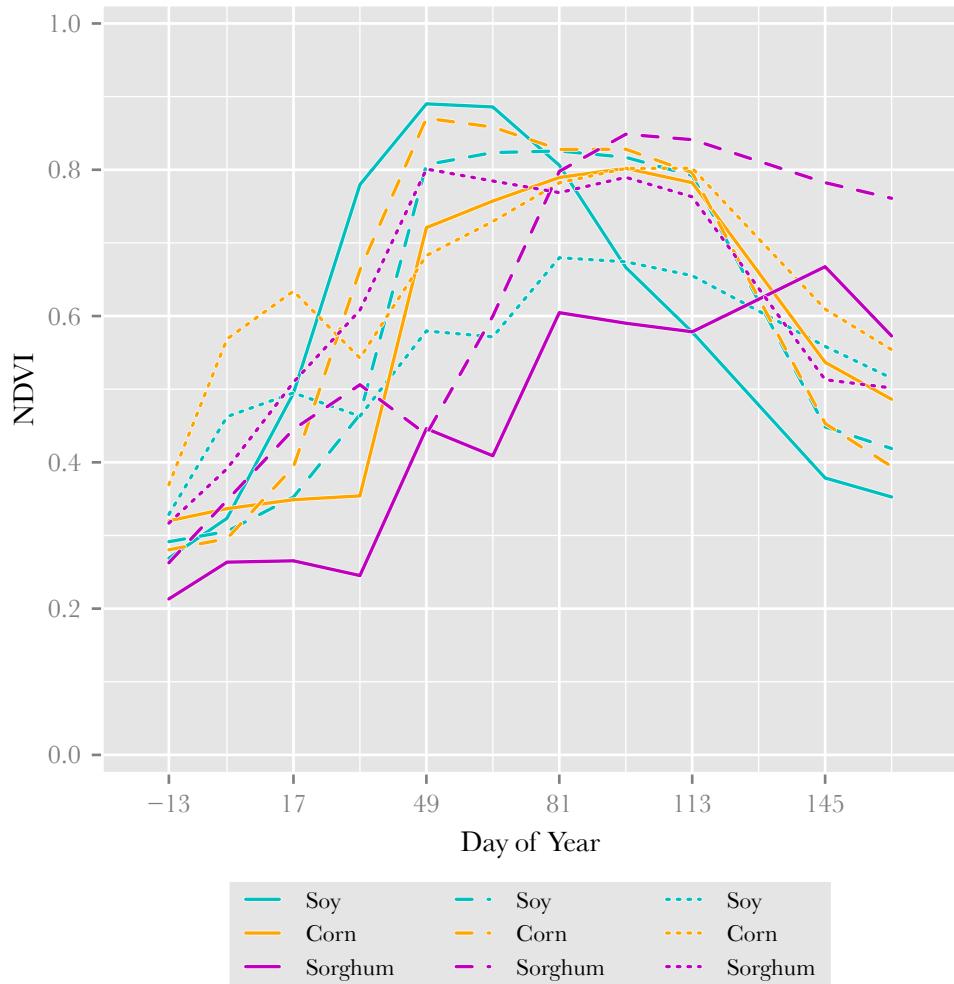

Figure 6.2. Corn, Soy, and Sorghum Signatures Extracted from the Pellegrini TSI

These are the signatures from the k-means crop clusters found in the Pellegrini TSI. While some strange exceptions like Soy_3, Sorghum_1, and Sorghum_3 deviate from the rest, the overwhelming similarities between signatures of different crops is striking. Unlike the crop signatures from Kansas, Pellegrini's crops are not temporally separated, but peak almost simultaneously.

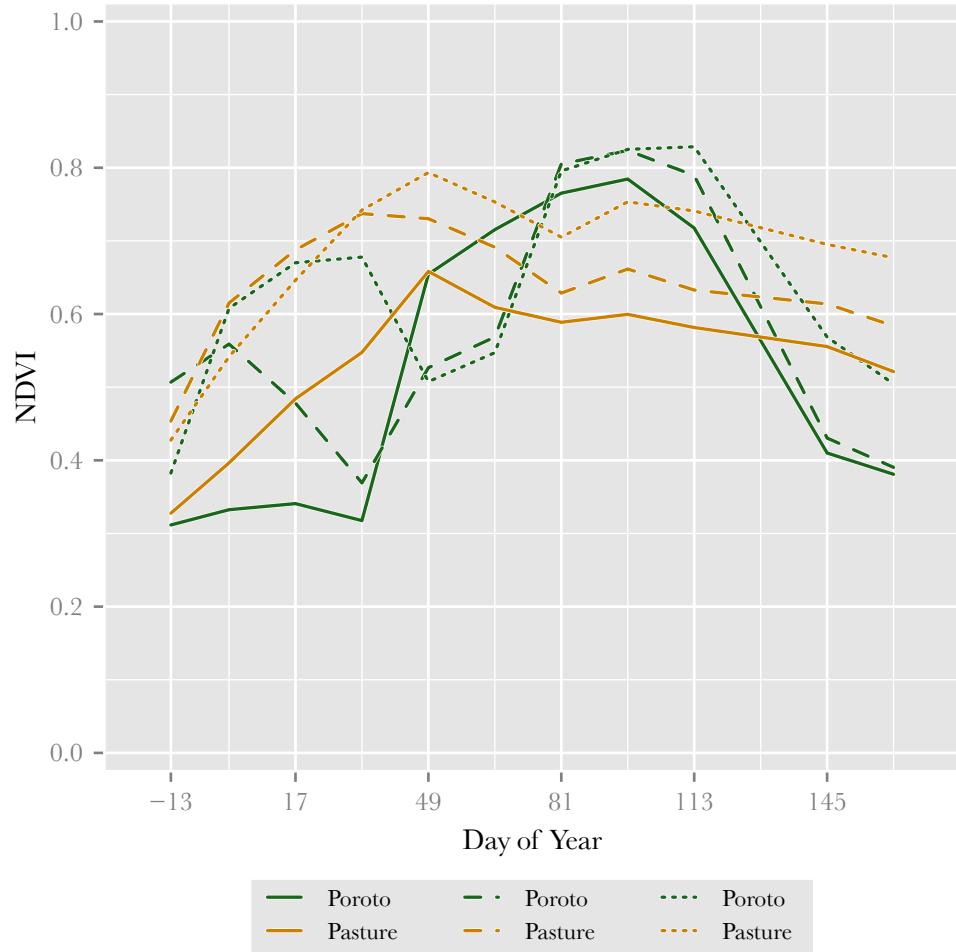

Figure 6.3. Poroto and Pasture Signatures Extracted from the Pellegrini TSI

to temporally align themselves with the pixel values. However, there is one problem with that idea: my method deals with similar-looking signatures, like corn and soy, by making an assumption that each should peak within different time ranges. In Kansas, corn peaks before soy, and as such they can be differentiated. Planting dates for Argentina as a whole also suggest corn should peak before soy. However, in Pellegrini specifically, the weather conditions and consequent agricultural practices do not allow this assumption to be met. When both crops peak about the same date, their temporal signatures are not significantly

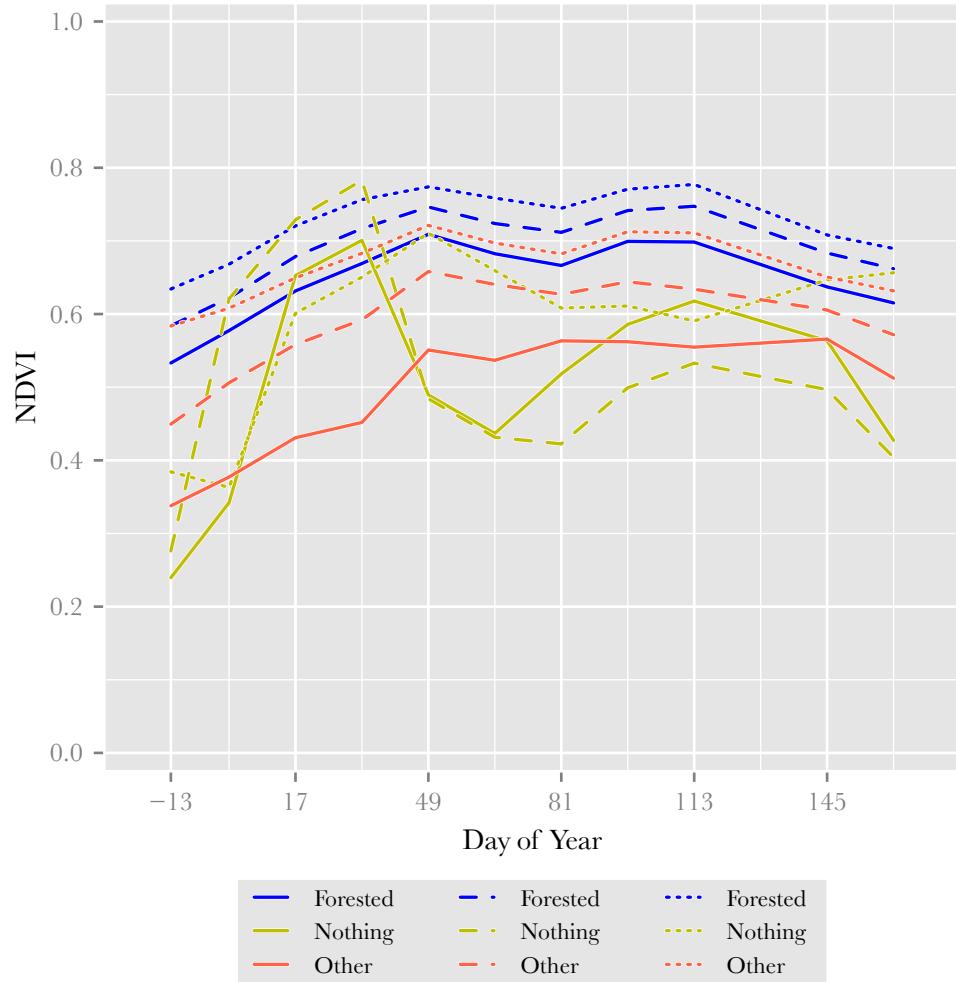

Figure 6.4. Forested, “Nothing,” and “Other” Signatures Extracted from the Pellegrini TSI

different, leading to the class confusion exhibited.

I believe higher temporal resolution data might create more detailed temporal signatures, which could allow for more difference to be detected between different crops. Combining such data with certain noise-filtering methods may allow signatures to be smoothed in ways that might accentuate differences between similar crops like corn and soy (see Doraiswamy, Akhmedov, and Stern (2006) and Sakamoto et al. (2010) for examples of higher temporal

resolution data and filtering).

Notes

¹I heard a few names for a few different types of pasture grasses that were being grown in the area, but I believe the two most prevalent are known locally as *gatom pani* and *grama*. I have not been able to determine if *gatom pani* has an english name; it is possible that I did not get the correct spelling. Blue Grama Grass (*Bouteloua gracilis*) is a common forage grass native to North America, though I am unsure if it is the same plant grown in Pellegrini. I did not learn much about any other pasture grasses cultivated in the area, or about typical harvesting practices.

²Even if soy had peaked earlier than corn, I would not have been able to achieve an accurate classification with the current tools, as corn-before-soy is a key assumption. That is, a single *tshift* parameter is specified for all reference signatures. It would be possible to rewrite the tool to allow different *tshift* values for different signatures, which might have sufficed if soy did peak before corn, but does not help when the peaks are coincident.

Chapter 7

Conclusion

Deforestation in Argentina continues despite regulations intended to put an end to the loss of native forests. Popular perception holds the rapid expansion of soybeans throughout the country responsible for the rush on agricultural land and consequent pressure on forests. Because of this, I wanted to develop a remote sensing toolset that would allow better study of agricultural crops in the region by classifying crops by crop types.

I believe I have successfully developed such a toolset. However, my results do not show that it can be used effectively to classify crop types globally and under any conditions, as I had originally hoped.

Agricultural practices are key assumptions in the design of any crop classifier. When differences in crop planting and management violate these assumptions, the classifier, and all other similarly-assuming classifiers, break down. The importance of a complete understanding of agricultural practices in the study area must not be underestimated. Such an understanding allows one to choose an appropriate classification method given the conditions. In the case of my work in Pellegrini, the assumptions of my classifier did not match the growing conditions, and the classifier was unable to differentiate the summer crops I

wanted to identify.

Rigorous testing and optimization of the classification tools and workflow developed in this study may eliminate some of the current assumptions. I believe such work can only improve classification accuracies and the conditions under which this classifier is useful. Many ideas for testing and future research are presented in Appendix D in the hope that other researchers will continue this investigation. I am encouraged by the results of this study and see these methods to hold promise for those investigating agriculture and land use and land cover change. Having said this, I must admit my recognition of the importance of this work has changed somewhat.

I initially thought that classifying specific crops is necessary to understanding the full dynamics of deforestation. While I still believe that to be true, my perception has shifted because if my experience in Argentina, and the data I have gathered. Knowing which crops are highest in demand and expanding most rapidly is often enough to get a picture of the pressures driving agricultural expansion; knowing what is being grown in a field in any given year is not as important as I thought. Why? Farmers can change their crops annually, so where soy is occurring one year, corn or sorghum or some other crop entirely may be grown the next, as the shift from soy to corn in Pellegrini may demonstrate. However, accurate land-cover maps generated by remote sensing methods could be used for LULC change studies and modeling that would provide insights into the actual drivers of LULC change.

Moreover, I have an newfound understanding of the influence of economics in LULC change. Popular wisdom in Argentina recommends two investments for securing wealth: buy dollars, or buy land. Correspondingly, agricultural land prices are extremely high (Mer-

coPress 2010); I was quoted \$20,000 USD per hectare for land around Nueva Esperanza. Prices in the more productive Pampas region are higher still. Anecdotally, one Pellegrini land owner, who resides in Rosario, told me he bought 3,000 hectares in Pellegrini for the same price fifty hectares of land surrounding Rosario was selling for.

Even so, many large parcels in the area were for sale; I cannot count the number of times I was offered a “good deal” by some land owner looking to cash in and get out. I was left with the impression that the deforestation, the mad land grab, is not about agriculture. It is about desperately securing wealth in the unstable Argentine economy, where inflation runs rampant and a shadow economy rules all. It is an investment bubble. And it just so happens to be threatening the ecological health of the country, and the planet as a whole. Perhaps it will burst, and the cutting will cease. But by then will it be too late? Will a consequent fall in production simply begin to inflate a new bubble somewhere else?

Appendix A

The Story of My Field Work

In order to complete an accuracy assessment of the classification I was to produce of agriculture in Pellegrini, I knew I needed ground truth data with which I could compare my results. As I suspected would be the case, I was unable to find any extant datasets, so I knew I would have to visit Pellegrini to gather such data.

After extensively reviewing satellite imagery of the area, I knew the fields were very large and appeared to have many roads connecting them, so I did not expect access to be problematic. While the size of the department, 6,943 square kilometers, is about the size of Delaware, I thought I would be able to cover ground fairly quickly, and allocated three weeks of time in Pellegrini to gather all my data.

I did have concerns to how the local people would take to my project. I know that I would be immediately suspicious of some foreigner coming in to my town and wanting to know everything about the agricultural practices in the area, including visiting all of the fields. I actually practiced how to say, in Spanish, “Don’t shoot! I am leaving, there is no problem.” Perhaps this is just an American thing, but I was expecting, at some point, to be confronted by someone with a gun who did not like me. After all, I am not necessarily in

favor of the agriculture that is taking over the area, and while I tried to present my views as neutrally as possible, I thought a conflict would be inevitable.

I arranged for a small rental car in San Miguel de Tucumán, Tucumán, a city about 150 kilometers from Nueva Esperanza. I knew the roads would not be great, but I figured I should be able to get through just about anything with the rental car, except mud. Nueva Esperanza was to be my base, and my plan was to try and visit the furthest areas first, as I expected those to be the most difficult to access, leaving the easier areas for last.

Getting to Nueva Esperanza was a challenge in itself. Due to the budget fare the airline provided me in exchange for my miles, it took me some 36 hours just to get to the hostel in Buenos Aires. Once there, I had to make my way around town to gather some supplies and change money. I had a short night in the hostel, as I needed to make an early flight from Buenos Aires to San Miguel de Tucumán. I picked up my rental car at the airport in Tucumán, at which point my stress level increased significantly, as I now had to make my way around the city not as a passenger, but as a driver. Argentine traffic laws do exist, but my perception is that, generally speaking, no one knows what they are.

Another problem was gas. Even something as simple as purchasing fuel for one's vehicle can become a new and stressful experience in a foreign country. After visiting Guatemala, where drivers would pull up to random buildings around town and attendants would appear from nowhere with a container of gasoline and a makeshift funnel made from the top of a plastic bottle, I was unsure what to expect. It turned out that the process was not so rudimentary nor much different from buying fuel back home, and my concern was mostly unwarranted.

After driving throughout the city gathering supplies, it was time for me to head to Nueva Esperanza. Despite using two maps and my GPS to try and navigate my way to the correct highway, I found myself on the wrong road out of town, and had to spend an inordinate amount of time following a long string of slow moving cars along what seemed more to be a series of main streets through a corridor of small towns than a highway. Fortunately, the road eventually led to the route I initially intended to take, and I began to make more rapid progress towards Nueva Esperanza. Unfortunately, my rapid progress quickly slowed upon reaching the beginning of road construction, which persisted the next 70 km or so.

My first full day I was in Nueva Esperanza I planned out a long route to investigate, but, after talking with some of the workers of the hotel I was staying in about my security concerns, I decided I should visit the police *comisaría* to ask if I was going to have any problems with land owners or locals while working. The first moment I opened my mouth I became the attention of everyone in building. I used the best Spanish I could muster to try to tell them what I was there to do and why, but I kept getting passed from person to person. Eventually, based on the questions they were asking me—things I was sure I had already said—I realized they could not understand me. And I was struggling mightily myself to understand them.

After some two and a half hours and what must have been forty people trying to interviewing me, the police were finally able to track down an English teacher who taught in the local schools. With his assistance, I was able to communicate the details of my project, and the police made up an official document vouching for my identity and purpose in case anyone took issue with my presence in the department. Everyone assured me that I would

not have any problems with the people. Not once during my trip did I need the document.

In spite of the late hour I left the police station that first day, I naïvely attempted to complete the long route I had laid out for myself. My early progress was actually quite good; I did not check off many points, but I was able to visit quite a number of fields in a short amount of time. This served only to errantly bolster my self-confidence.

In line with my plan to visit the furthest points first, I was making my way to the far northwest corner of Pellegrini. About an hour and a half from Nueva Esperanza, I came to the border with the province of Salta. Looking at the Landsat imagery, I could clearly make out a long, straight road following this line. That this road was not marked on any other maps should have been a clue to me.

After a few minutes of searching and considering the numerous side paths along the main road, I determined the correct road to follow, and proceeded to head north along it. I had a thought about the sandiness of the road, but knew that as long as I maintained my momentum I should not have any problems. I did not consider the hour, which was closing in on 5:00 PM, nor the fact that, due to my lengthy visit with the police, I had not taken the time to eat that day, aside from a breakfast consisting of a lone banana.

A few minutes down the road, the situation quickly worsened. Deep ruts suddenly appeared in the middle of the road, and I did my best to straddle the car over the left one by attempting to drive with my left tires on the side of the road and my right tires down the middle. However, the success of this maneuver was short lived, and before I knew it, the small, low car had dropped down into the ruts. I stepped on the gas, hoping that keeping the car moving would keep me from getting stuck. The sound of the sand scraping at the

underside of the car was unbearable. I spotted a break in the vegetation on the left side of the road, so I pointed the car at it, hoping the wheels would be able to break free from the ruts with a sharp enough turn. Luckily, this time my maneuvering was successful, and I found myself parked on the only hard patch of clear ground in visible surroundings.

I got out of the car and surveyed the situation. The deep, sandy ruts continued in both directions along the road. Being only a few minutes from the main road, and realizing the lateness of the hour, I figured the only reasonable course of action would be to return to Nueva Esperanza. I contemplated driving through the small brush along the side of the road to get back to where the ruts were shallower, but I figured my tires would have been no match to the large thorns common to so many of the Chaco's plants. My only regress would be to attempt to drive back the way I came.

Careful of the thorniest of plants, I managed to turn my car around, orienting it in the proper direction. I knew I needed to do two things if I were to make it back to the main road without problems: go fast, and stay out of the ruts. I was able to do neither.

I stepped on the gas, but given the gearing of the Chevy and its abysmally-small power plant, quick of the line it was not. Adding to the fact that I was wholly unsuccessful at keeping out of the ruts, I managed all of three or four meters before losing all forward momentum. I tried rocking the car by repeatedly shifting between first and reverse, but only managed to get the car more firmly planted in the sand.

Thanks to the sound advice of Polo, one of my committee members, I had actually purchased a shovel the day before in Tucumán. To say that at this point the shovel came in handy would be an understatement.

I proceeded to dig out all the sand underneath the car upon which it was high centered, as well as a short path both in front and behind the car, and attempted another run at freedom. I repeated these steps numerous times with no success. Each time I felt that much closer to collapse due my plummeting blood sugar.

Sometime into this cycle of failing to free the car, a woman approached on a motorbike with her two kids. I stood there, staring at her as she drew closer, hoping she would stop and tell me she would be right back with someone to help me out. Instead, she stopped and began looking at me as if amused, and I proceeded to explain my predicament as best I could. She told me in the most unhopeful manner that she would send someone my way, if she could even find someone capable of helping me. I still wonder what became of that woman and her two kids.

Eventually, I became wise to my insanity, and decided I needed to try another course of action. I recognized my problem was acceleration: each time I tried to accelerate, my tires would dig into the sand, and the ruts would present themselves as that much deeper. In order to escape the situation, I needed to be able to get my car to speed before I encountered any ruts.

I quickly went to work regrading a 30-meter length of road. By this point I was on the verge of passing out, but I knew I could not take a break. Even if it had dawned on me that I could have eaten one of my cup of noodles raw (the only food I had in the car due to a misjudgment in preparation for this day trip) I could not have stopped to do so. I needed to get myself out before dark or I would be stuck there all night.

After what I estimate to be two hours of hard work in the energy-sucking heat, I finally

managed to clear what I hoped would be a long enough section of road to get me free. Getting back into my car, I resigned myself to spending the night out there, my cynicism taking hold and condemning me an attitude of hopelessness. Yet, in spite of my natural inclination for pessimism, I found my car floating over the sand, making its way toward freedom. I did not let off the accelerator until I was sure I had loosed myself of the clutches of the sand.

At this point I felt as though my whole plan was falling apart. I had planned to visit some twenty-five points that afternoon, yet I only made it to four. I thought I could depend on myself to get around, but I realized my car was woefully incapable of passing all but the most traveled of roads. Moreover, many of the “roads” I had spotted on the satellite imagery and was depending on to get to my points were not in fact roads, but private paths behind fences, gates, and rows of bushes, accessible only to those with the permission of the landowner.

Even the roads that were accessible were beyond my worst nightmare. Perhaps my definition of bad was flawed; even when people told me before my trip the roads would be bad, I just said I’d be fine. I’ve driven on bad roads; what could be the problem? This is not to say I did not expect to have *any* problems with the roads, but to see the condition of the main roads—all potholed, rutted, sandy, and muddy—and to get stuck on my first day out, was a humbling and troubling experience.

I needed help.

The road conditions were not the only reason either. My interactions with the police officers at the comisaría should have been a clue to the difficulty I would have communicating. Argentine Spanish is particularly difficult on its own (if one has learned Mexican

and Central American Spanish as I have), but the Spanish in Pellegrini is another dialect entirely. Take Argentine Spanish, add indigenous terms and the accent and idioms of an isolated rural area, and I felt like I was trying to learn another whole language. If I could have chosen one thing to have made my trip smoother, it would have been a better command of Pellegrini Spanish. I was able to get by, and came to understand some individuals fairly well, but often I found myself unable to communicate effectively.

I became clear to me that I needed to break out of my comfort zone and rely on others. Doing so was very hard for me, as I tend to be extremely independent and am often unwilling to delegate. I set unreasonably high standards, and few, including myself, can live up to them. However, I was clearly not succeeding on my own; I needed people that could get me to the places I had to see. It turned out that the English teacher just so happened to have a motorcycle, and graciously agreed to take me out to survey points in the afternoons when he had free time. He also introduced me to a local teenager, who, despite his age, proved to be a worthy guide, as he knew the area and some English. His grandfather also had a truck, which helped us get around.

In working with these guides, I quickly came to learn that I was going to have the best success not in going to every survey point myself, but in talking with local farm hands and landowners. Even with the right vehicle, many places were still inaccessible, primarily because many “roads” on the satellite imagery didn’t connect, or were blocked by locked gates. Luckily, I was also introduced to this police officer, who was of particular value to my project because he was responsible to know everything and everyone in Pellegrini. Not only did he know what roads I could and couldn’t drive on in my car, but he also had a way with people

that allowed him to get much more information than anyone else I worked with. By far, the connections I made through him supplied the majority of the data I collected. One such connection was with his cousin. His cousin was not only exceptionally knowledgeable about agriculture in Pellegrini and managed quite a number of fields, but actually took it upon himself to gather some of my data for me, visiting some extremely remote fields and talking with a number of other producers he knew.

I suppose I knew, intellectually, that I would need to rely on local help, but knowing and doing are not the same. Trusting people—especially people I do not know—with a project as big and important as my master’s thesis took an intentional act of letting go. I had to realize I needed skills and knowledge I did not have, but those around me did. This was doubly hard considering my inadequate lingual skills that, at times, caused communication breakdowns. What’s more, I couldn’t decide who was going to help me: the people I preferred to work with were not always available, so I had to turn to others I would not necessarily have chosen. Anyone doing fieldwork must be prepared for this reality: you can’t choose the people that will be willing to help you.

The letting go and trusting did not come easy, and often didn’t really happen; I merely internalized my uncertainty in others as stress.¹ Yet, despite the overwhelming stress I inflicted on myself during some particularly “trusting” moments, *nothing bad happened*. I got my data. I was never robbed. I was never left stranded in the middle of nowhere (except of my own doing). My car got repaired and I didn’t get ripped off. I survived.

Another realization: you never know what someone might be able to offer you. That is, I found it important to talk with everyone around me, as hard as that was. Sometimes is was

merely a different perspective or insight, while other times it was information which enabled me to check off a few sample points, but everyone had something to tell me. I am an introvert and not outgoing, so I tend to shy away from most people, yet I was forced to interact with everyone. Many people I honestly would have avoided under different circumstances. I even found myself doing things that made me uncomfortable just to build my credibility, such as going to the *boliche* at three in the morning and trying (and failing) to dance to the popular music. Surprisingly, I ran into a couple landowners in the club that night, and I could tell their impression of me was positively affected just by me being there. Joining in the cultural customs builds a rapport better than anything else.

These activities and having to build relationships I would normally have avoided pushed me outside my comfort zone and were a great opportunity for personal growth. Reflecting back on the trip and my life since returning, I can see a greater degree of social confidence. I am still shy and introverted, but I no longer feel unable to put myself out there when meeting new people. Moreover, some relationships I might have otherwise written off turned into good friendships.

As is evident, I was overly confident in my abilities, and consequently made a number of incorrect assumptions about how my work would go. Thankfully, of all things, the data collection maps I made worked very well. If I were to have to plan such a project again, I would struggle to identify any changes I would make to them. I will say that I overestimated the usefulness of the maps for navigation; my GPS receiver with a satellite image and my sample points loaded onto it proved to work much better, as I didn't have to find my location on the map before identifying the next turn in the road. The obviousness of this strikes

me now; I am just grateful that I was able to download the necessary software, despite my phone's seemingly nonexistent data connection, to make such a solution possible. Next time I will be sure to have my GPS setup beforehand.

To reiterate: one must trust in others. They will help. I expected them to not. Perhaps that is because their culture is more relational, or perhaps I am simply too untrusting. In any case, it is foolish to think that one can go into another culture without the expert knowledge the locals have of the place and customs² and be able gather any data, whether those data are of the physical geography, of technical practices, of cultural customs, or of anything else. I had to rely on wonderfully helpful people to do that actual data collection; I felt little more than an observer.

Notes

¹Cultural differences were not helpful in this regard; everyone is extremely laid back; it felt as though few understood the time constraints of my work. However, I even found myself with such an attitude, most likely because of the effects of siestas and eating dinner well into the night; it is hard to get much done after midday. Additionally, the food was generally not my favorite. A lack of calories and sleep conspired to keep my energy levels depressed, so I was often content just to sit around and abide the relaxed atmosphere. Under other circumstances, I would have greatly appreciated this un-busyness. The constant assault of work is, I believe, a severe plight of the American culture, and the Argentine contentedness with leisure is refreshing. Under the looming pressure of a thesis, however, the inability of this environment to foster progress becomes problematic, and increased my stress levels.

Even when I was full of energy and vigor and wanted to get things done, I was often unable to do so, because of my reliance on others who were often occupied. While I felt as though I was not doing enough, I believe they felt like they and I were doing too much. Near the end of my trip, with unfinished work looming before me, I was often told that I needed to stop stressing and relax, yet the relaxing was exactly the cause of my stress! Of course they were right though, as everything was finished in time, thank in no small part to all those who worked to help me complete my project.

²Even the simple—and apparently not universal—act of knocking on the door when visiting someone's home: what is one to do when fences, dogs, and sometimes the absence of a front door prevents knocking? Clap of course. While clapping seems an entirely logical

course of action after the fact, it was not initially obvious to me, and I found my ability to collect data severely limited until I understood this, and a few other, basic rules and customs regarding social interactions.

Appendix B

Developing the Processing Tools

Development has been a very iterative process, and has been primarily driven by testing requirements (see Appendix C). Many of the core functions began as simple proof-of-concepts. As the codebase grew, it underwent significant refactoring. As this is my first major development project, I had to learn—the hard way—how to properly structure a project of this nature. I arrived at many key design principles quite late; some pieces of the project, consequently, were rewritten multiple times. Simultaneously, testing necessitated better ease of use and increased functionality; many features, such as the command line interface to the tools, were added as the need arose and better code organization made implementation possible. With the code as it currently stands, I believe my tools are just as easy to use as GDAL.¹

B.1 Review of the classification process

To reiterate, classifying imagery is a multi-step process. To do so is roughly as follows:

1. Build a multi-date image stack or time series image (TSI) from single-date images.
2. Find “pure” or mostly “pure” TSI pixels (eliminate mixels).

3. Obtain a reference temporal signature for each of the crops to be identified in TSI.
4. Run the fit algorithm using the phenological reference curves to generate RMSE rasters for each of the input reference signatures.
5. Use the threshold tool to find the optimal RMSE threshold for each of the RMSE rasters (requires ground truth data for accuracy assessment). This process outputs the final classified image.

Steps 1, 3, 4, and 5 have been implemented as command line tools, each of which is detailed below. Step 2 is currently a manual process, the procedure for which is detailed in section subsection 4.3.3 on page 33; how this step was established is explained in section C.2 on page 98. A few other command line tools, such as to plot signatures or to create masked rasters, were also developed, but are not described here. The full source code for the project is hosted github: <https://github.com/jkeifer/pyHytemporal>.

B.2 Creating Time Series Images

Before I could complete any testing, I had to first determine a way to create a chronological multi-date image stack—a time series image (TSI)—in which the values of each pixel represent the temporal signature of its contents. A TSI can be thought of as the temporal equivalent of a hyperspectral data cube, and is the primary data structure used in the analysis.

Despite the fancy terminology, however, a TSI (or hyperspectral data cube, for that matter) is merely a multi-band raster file, where each band is the data from a given date (or for a spectral band, in a data cube). Abstracting this concept a step further, a raster file is simply an array. A single-band raster is therefore a two-dimensional array where the

columns and rows of the image are represented by the columns and rows of the array, and the data are single-dimension values in each cell. Adding multiple bands, or in this case dates, to the image is easily accomplished by adding another dimension to the array.

The Python Geographic Data Abstraction Library (GDAL) and numpy libraries include objects and methods which make opening spatially-enabled raster files as arrays, saving arrays to spatially-enabled raster files, and manipulating arrays in memory trivial tasks. Thus, creating a tool to build a TSI from a selection of single-date raster files was straightforward and easy, and did not require any extensive or involved testing.

The finished tool I call the Build Multidate Image tool. It simply requires the user to specify a directory containing the MODIS .hdf files that will be assembled into a TSI. Users can specify which VI the tool should extract from the .hdf files as an optional argument; the default is to use NDVI.

B.3 Extracting Reference Temporal Signatures

I hope future libraries of temporal signatures will allow researchers to use temporal classification tools without needing to derive their own signatures. Unfortunately, such resources are not available now. The lack of these resources necessitated that I devise a tool to create such signatures. I named this tool the Extract Signatures Tool (EST).

I decided, in order to maximize ease of use, the tool would need to use a vector dataset set of points as the input. For each point, the tool finds the TSI pixel coordinates, then extract the point's temporal signature. Averaging the signatures extracted from each point gives the reference signature for that class, which is written to a file for later use.

To implement this solution, I created a library to read point features from shapefiles. This library included a function to take the geographic coordinates of each point in a shapefile and convert them into a list of pixel coordinates in a specified image. I wrote a set of functions to read a pixel's value from each band in a multi-band image using a list of pixel coordinates. The extracted values are saved in memory and in a text file for later use. Another function finds the mean value for each band, writing the result to another file with the format shown in Figure B.1. These functions allow a user to read in the values of a class of pixels in a TSI defined by a series of points stored in a shapefile. Then, the user can find the average values across those points, which is the reference temporal signature of that class. Each of the text files was in plain-text ASCII format, and I decided to use the file extension .ref.

I based the formatting of the .ref files on the .sig files used by ENVI for hyperspectral signatures. Using a plain-text file-based data format currently seems to be the best solution for storing reference signatures, as the data are very simply structured and files are highly portable. However, future implementations of the EST may benefit from a more rigid or better contained data format. In particular, a format that supports storing multiple values per date would allow multi-date, multi-band analyses.

B.4 The Fit Algorithm

Developing the fit algorithm and the corresponding tool was a more complex problem. As described in section 2.4 (page 10, the basis of the algorithm is Equation 2.3. The equation finds the average difference between a pixel signature and a reference signature (the RMSE),

Figure B.1. An Example .ref File Used to Store Reference Temporal Signatures

Comments are marked by // and each non-comment row represents a VI value (right column) for a given DOY (left column), separated by a space.

while allowing the reference be transformed within predefined bounds. Minimizing the equation enables the degree of fit between a reference signature and a pixel signature to be quantified. To implement the algorithm, I decided to use scipy's minimize function. I began by building the simplest implementation possible, while making as many parameters as possible into arguments of the enclosing function to allow future testing. I continued building out the functionality until I had a tool capable of reading in a TSI from a file path and reference temporal signature .ref files in a directory. The tool could then process TSIs using signature .ref files, and output a RMSE raster corresponding to each signature. The value of a pixel in a RMSE raster is the RMSE between the reference temporal signature

and the same pixel in the TSI.

One clear problem early on was speed. Python's global interpreter lock (GIL), intended to increase the security and reliability of running python code, also has the consequence of limiting code execution to a single processor core. With current multicore processor designs, the GIL prohibits python from using much of the available processing resources. For example, in my eight-core computer, I was limited to using only 12.5 percent of its processing capabilities. Consequently, I could only process a single signature file at a time. Processing five reference signatures required each RMSE raster to be produced consecutively, despite available cores in my CPU.

To get around this, I redesigned the tool to allow the use of the python multiprocessing module. With multiprocessing, I was able to spawn a new worker process for each reference signature used (limited to a maximum number of processes as specified by the user). Each process could use an entire core to produce an RMSE raster. At first, this seemed to be a great solution: when using five reference signatures, I could simultaneously produce all five RMSE rasters in one-fifth the time. However, the parallel use of resources is not as straightforward as it seems.

In the later stages of testing, I began getting a serious error when attempting to generate the RMSE rasters. I am unsure why the problems began; it may be related to refactoring the code. I know that it had not occurred in earlier testing as the issue resulted in a fatal error, where the program would try to read in a pixel from the TSI and would get a null value. Strangely, this issue would always happen on the twentieth row of the TSI. Even stranger, printing the pixel value to the screen would not get a null value. The program

would continue without errors, but careful investigation revealed that the value returned from problem pixels would not be valid (often being zero for every band, or a repeating pattern of negative numbers).

I tried eliminating the parallelism problem by using just a single worker process. Thus, the same code would run, but with only a single process trying to access the GDAL image object in memory. Preventing concurrent access to that object had the intended effect, and the problem disappeared. I tried using the multiprocessing lock construct to prevent multiple processes from reading the image object simultaneously, but this had no effect. Finally, after reading the multiprocessing documentation yet again, I decided I would try reading the TSI into an array in memory, as arrays seemed to be safer in concurrent applications. With this change, the problem vanished. Additionally, this solution had the benefit of providing a moderate speed boost. Unfortunately this solution also raises the memory requirements of the program: the entire TSI must be read into memory, and all the arrays for the output RMSE rasters are also in memory. The memory footprint, consequently, is roughly equal to $s(n + 1)$ where s is the size, in bytes, of the TSI image, and n is the number of worker processes.

Another problem I had throughout development involved pixel coordinates. Numpy arrays use matrix-style coordinates in row-column order, while GDAL functions require coordinates in terms of x-offset and y-offset, which is actually column-row order. This problem was especially pervasive during refactoring, because I would switch from GDAL objects to images stored in arrays to boost efficiency. Then, if I didn't change all the other calls to that object, I would end up accessing pixels with the wrong coordinates.²

Using the algorithm is easy, as it has a command line interface through the Find Fit Tool. Due to the numerous parameters required by the algorithm, the command has many options. However, it only requires that the user specify the path to the TSI image, the path to the directory containing the .ref reference signature files, and the start day-of-year and day-of-year interval for the TSI. All of the other options require user input only if the user wants to use a non-default value.

B.5 Creating a Classification From the RMSE Rasters

Merely finding the RMSE rasters does not a classification make. The first step in creating a classification is to find useable RMSE values; even pixels that are obviously different than a reference signature will result in a RMSE value. Thus, the RMSE rasters need to be thresholded to eliminate high RMSEs.

Choosing a value at which to threshold the RMSE rasters is not a simple decision. One can think of the threshold in a similar manner to weighting: a higher RMSE threshold will allow more pixels from that RMSE raster to be considered in the final classification. The correct threshold for a RMSE raster will vary depending on a variety of factors, including what types of crops are in the sample area, what crops are trying to be identified, and how homogeneous the pixels for that crop are in comparison to the reference signature used. The extent to which these and other factors influence the optimal threshold is not well understood and requires further study. Despite not knowing the exact effects of these factors on the optimal threshold value, it is clear that the optimal value will vary between RMSE rasters. That is, a single value used across all RMSE rasters in a classification is unlikely to

provide the highest possible accuracy.

Once the RMSE rasters are thresholded, one can make a classification by finding the best fit for every pixel. For example, if a given pixel had thresholded RMSE values for corn, soy, and wheat of 356.7, 531.5, and none (as the original RMSE was above the threshold used), respectively, the best fitting signature would be corn, and the pixel could be classified as corn. If a pixel did not have any RMSE values under the threshold used, then that pixel would not be classified (a classification as “other” would be equally correct).

In order to automate this thresholding/best fit process, and to provide a means to quickly iterate through possible RMSE threshold combinations, I created a command line tool called the Classify Tool. The tool requires the user to specify the RMSE rasters to be classified, a truth raster, and RMSE threshold parameters. The threshold parameters allow the user to specify the starting RMSE threshold value, the number of RMSE threshold steps to test, and a RMSE threshold step value (how much to increase the threshold each step). The truth raster is ground truth for the entire classified area, and is assumed to match the RMSE rasters’ pixel grids exactly and cover the same geographic extent (such that every pixel coordinate in the RMSE rasters and truth raster will describe the same geographic location and extent). From these parameters, the tool will automatically generate every possible threshold combination. Then, the tool will brute force through those combinations, creating a classification with each and checking the accuracy against the truth raster. Once completed, the tool will output a classification raster created with the highest accuracy combination, as well as a report detailing every combination tested with a confusion matrix for each.

Notes

¹Which, quite honestly, is probably not that easy for most, but should be manageable for anyone with command line experience.

²One piece of advice to anyone developing raster tools: do not use square test rasters. Doing so hides many such bugs. For example, if the pixel coordinates are accidentally supplied in row-column format when a function is expecting column-row order, a square image will never throw an error, whereas a rectangular image will result in an error when the index of the array is out of bounds. Many otherwise subtle programming errors can be caught this way.

Appendix C

A Breakdown of all Completed Testing

C.1 Round 1 Testing: Initial Classifications

Testing Considerations

I began testing the toolset (explained in Appendix B) with three main questions. I wanted to know how the accuracy of classification is affected by:

- The spatial distribution of pixels chosen to create the reference curves.
- The temporal distribution of pixels chosen to create the reference curves.
- The VI used for the classification.

To test these factors, I chose six small study sites dispersed across Kansas, each 100 MODIS pixels square, or about 2.3 square kilometers (Figure C.1). Using the USDA CDL as reference, I identified areas containing a mix of corn, soy, sorghum, winter wheat, and winter wheat/soybean double crop pixels. I did my best to distribute the study sites across the state to capture a wide variety of growing conditions. This task was surprisingly difficult, given the large extent of the state and the concomitant variation in growing conditions. The crops favored tended to change from one area to another. For example, few areas in western Kansas had little more than corn and wheat.

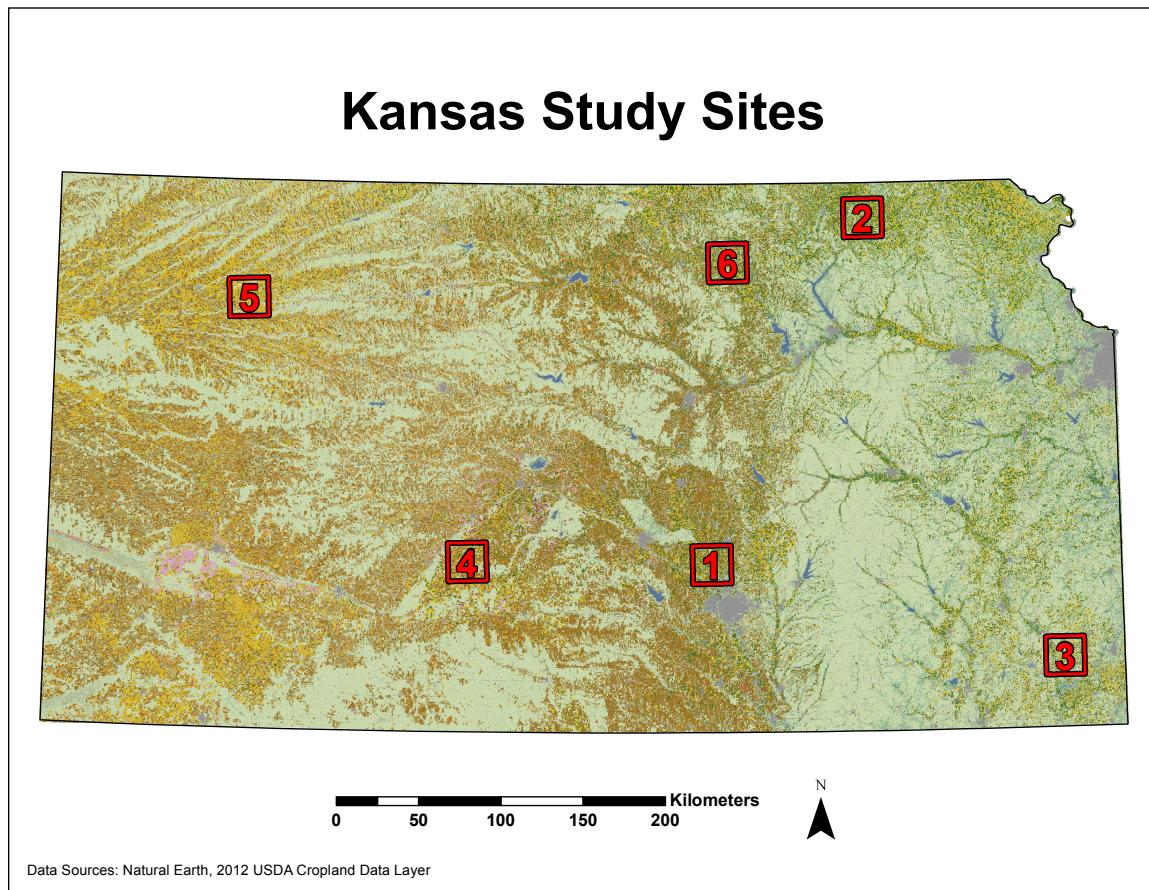

Figure C.1. The Six Kansas Study Sites

Next, I assembled a TSI for all of Kansas from summer 2012 MODIS 16-day NDVI composite imagery, as described in subsection 4.3.2 on page 32. I also used the same procedure to create a Kansas TSI using the MODIS EVI composites. I clipped smaller, individual NDIV and EVI TSIs for each of the six study sites from the larger Kansas image.

Within each study site, I found four to eight TSI pixels of corn, soy, sorghum, winter wheat, and winter wheat/soy double crop. I took care to choose only pixels in the center of fields, under the assumption such pixels would be more representative of each crop's true temporal signature. On each chosen pixel, I digitized a vector point feature (see Figure C.2 for an example from study site 1). I separated the points in separate shapefiles for each crop

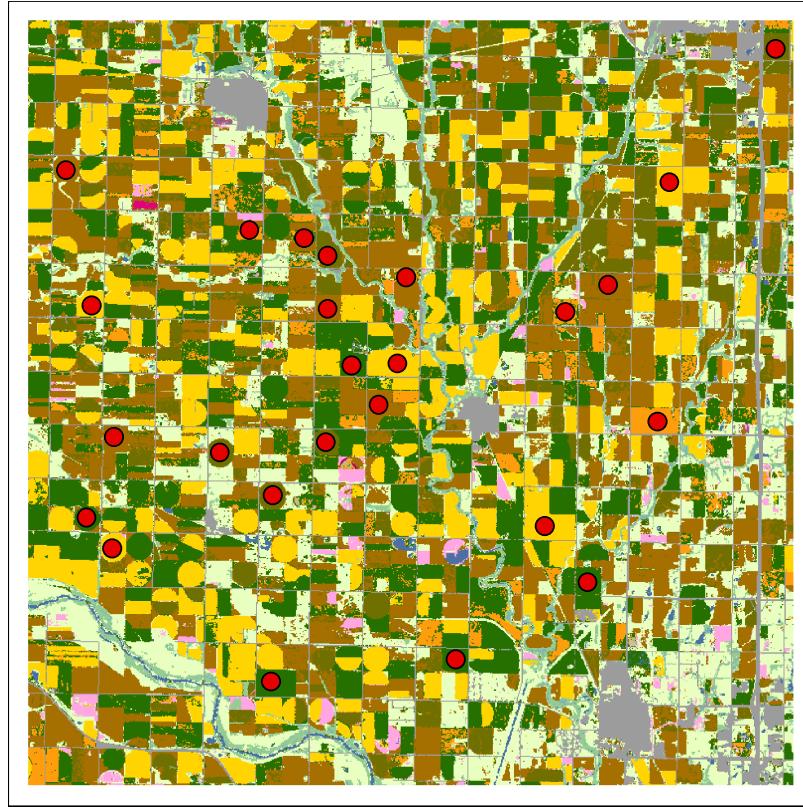

Figure C.2. Points Marking Pixels Used to Extract Reference Signatures in Study Site 1

in each study site. I used these shapefiles as inputs to the RSG. Both NDVI and EVI reference temporal signatures were extracted in each study site TSI. Averaging the six extracted NDVI reference signatures for each crop gave me NDVI reference temporal signatures averaged across all six study sites. I also did the same averaging of the EVI signatures.

I created seven classifications of the EVI TSIs for each of the study sites: one classification using the study site's own reference signatures, five classifications of the study site, each one using the reference signatures derived from one of the other study sites, and one classification using the mean reference signatures averaged across all of the study sites. I repeated this procedure to produce an additional seven classifications of the NDVI TSIs of each study site. For all of these classifications I used only the corn, soy, and winter wheat reference

signatures.

By assessing the accuracy of these classifications I could test two of my initial questions: how the spatial distribution of pixels used to construct reference signatures affects the accuracy of classification, and which of the VIs had better performance. For the spatial distribution testing, I determined there could be four possible outcomes:

1. *Reference signatures are usable between study sites, but averaging multiple sites increases classification accuracy.*

Classification accuracies will be largely independent of the reference signature set used. However, the mean reference signatures will produce a higher classification accuracy than those derived from single study sites.

2. *Reference signatures are usable between study sites, but averaging multiple sites decreases classification accuracy.*

Classification accuracies will be largely independent of the reference signature set used. However, the mean reference signatures will produce a lower classification accuracy than those derived from single study sites.

3. *Reference signatures are not useable between study sites.*

Classifications using reference signatures from different study sites will have consistently lower accuracies than the study site's own reference signatures. The mean reference signatures will perform somewhere between those of the study site in question and those of the other study sites.

4. *Spatial distribution has no effect.*

The classification accuracies will be relatively consistent no matter which reference signature set is used.

I initially hypothesized that averaging signatures across multiple sites would decrease the “truthfulness” of the reference signatures. That is, geographical discrepancies in season start date, maximum VI intensity, and/or season length would skew the resultant mean

reference signature away from a “true” reference signature. Such skewing should negatively affect classification accuracy. I therefore expected outcome two.

As for my third question (about temporal variation in the construction of reference temporal signatures), I decided to wait and see what results I got from these tests. If I found a wider spatial distribution of pixels negatively affected the classification accuracies, then I could reasonably conclude adding a temporal component would have a similar outcome: temporal variance, like spatial variance, would introduce discrepancies in season start date, maximum VI intensity, and/or season length.

Round 1 Results and Discussion

The accuracies of the fourteen classifications testing the spatial distribution of reference signatures and the performance of the two MODIS VIs is shown in Table C.1. Some clear patterns are immediately obvious. First, none of the classifications had a very high degree of accuracy; study site 3 stands out with much higher accuracies than the rest. Secondly, NDVI resulted in a higher top accuracy for every study site. Thirdly, aside from study site 5 in the EVI-based classifications, each site’s highest accuracy occurred when its own signatures were used for the classification. Lastly, generally all of the mean reference signature classifications are between the lowest and highest accuracies for each study site.

A more detailed examination of study site 3’s results shows that the increased accuracy is due to the fact that relatively few of the pixels in the study site are crop pixels (Table C.2). A higher accuracy thus results because so many pixels were left unclassified as “other.”

As for NDVI versus EVI, the results show that NDVI consistently has higher classifi-

Table C.1. Overall Percent Accuracy for Each Round 1 Classification, by Study Site (SS). Green cells indicate highest accuracy for each SS.

EVI							
	SS 1	SS 2	Reference Signatures	Source	SS 6	Mean

	Overall Accuracy: 78.69%						
	Kappa: 0.49						

cation accuracies. For this reason, I chose to continue all the following tests using NDVI. However, the EVI results were not far behind, so I am hesitant to conclude that future optimizations could not make EVI-based classifications as or more accurate than NDVI-based classifications. Further testing is required in this regard.

That each study site had its highest accuracy classification using its own references signatures was probably the most significant finding of the test. This result was not wholly unexpected: even if temporal signatures are largely location-independent, there is likely to be some location-specific phenomena influencing the shape of the signature curves. In some cases, it appears that some classifications using other study site reference signatures were of similar accuracy. For instance, the study site 1 NDVI classification using study site 4's signatures has an accuracy of 60.7 percent, versus 61.1 percent with study site 1's own signatures. However, in all other cases (using signature from study sites 2, 3, 4, 5, and 6), the study site 1 NDVI classification accuracies are about 10 percent lower.

The accuracies of the mean reference signature classifications are generally low. They are never the worst, which may suggest that it is better to average a greater number of pixels together if the representative-ness of the chosen pixels cannot be established. However, this conclusion would support a more selective and refined approach to creating reference signatures: don't try to average out bad pixels, eliminate them in the first place.

Looking back on the outcomes I outlined above, I actually found none of them completely captured the behavior shown in the results. I did not see relatively consistent classification accuracies independent of the set of reference signatures used, but I also found that the reference signatures from some study sites did well at classifying others. The mean

signatures were also somewhat in the middle: generally they did not do terribly well, but sometimes came close. The best interpretation I could make of these results is that, under the right circumstances, reference signatures can be used to classify other areas. However, the cases where the reference signatures were not portable were concerning, as were the low overall accuracy levels. I began to consider that I might not be able to answer the initial testing questions. Instead, I realized I needed to take a step back and better explore what factors affect the classification process.

C.2 Round 2 Testing: Eliminating Mixels

Pre-testing Investigation

I began my Round 2 testing by diving back into my Round 1 results. I wasn't sure exactly what I needed to test, but I knew my previous results held more clues. For the sake of simplifying my investigation, I decided to focus solely on study site 1 (SS1) for the remainder of my testing. If I could boost the accuracy of its classification, I would identify some of the factors influential in the classification process. I chose SS1 over the others as it has the best variety of crops in which I am interested, and also includes some large non-crop areas of different land cover types. This mix seemed to offer the best testing environment.

First, I studied the classification results for SS1 from Round 1 produced with its own reference signatures (Figure C.3). I noticed that the major patterns generally matched the CDL fairly well. If the classification *looks* correct, however, where were the errors? Obviously there should be many incorrect pixels, as this classification only had an accuracy of 61.1

percent. Yet they weren't obvious at first glance.

To find these incorrect pixels, I created an image with of the correct pixels and an image of the incorrect pixels (Figure C.3c and Figure C.3d). In the former, I noticed that many of the black incorrect pixels seemed to fall on the edges of fields. In the latter, I noticed some class confusion, a finding reinforced by the confusion matrix for this classification (??).

table of ss1rl confusion matrix

The class confusion seemed to be a problem, but how to begin to remedy it was not obvious. That so many border pixels were incorrectly classified, conversely, suggested that this classification method struggles when pixels have more than one land cover. Such “mixed-pixels” are often termed “mixels.”

The problem with mixels is that each land cover in a pixel has a different temporal signature. The different signatures are aggregated at the pixel level and become mixed, creating a new signature representing that specific mixture of individual signatures. This problem is not unique to my temporal data; all raster land cover data have mixels. Users of spectral data even have spectral unmixing tools to extract subpixel spectral information.

In my case, the large size of the MODIS pixels increases their possible effect on classification accuracy. Many different land covers can be included within a 231-square-meter area. The large pixel size also means that a much greater percentage of the study area is composed of mixels than if a smaller pixel were used.

For these reasons, I hypothesized the low classification accuracy was partially because mixels could not be processed accurately by the fit algorithm. In other words, if two (or more) crops are mixed within a pixel, the curve of that pixel's values will be a blend of both

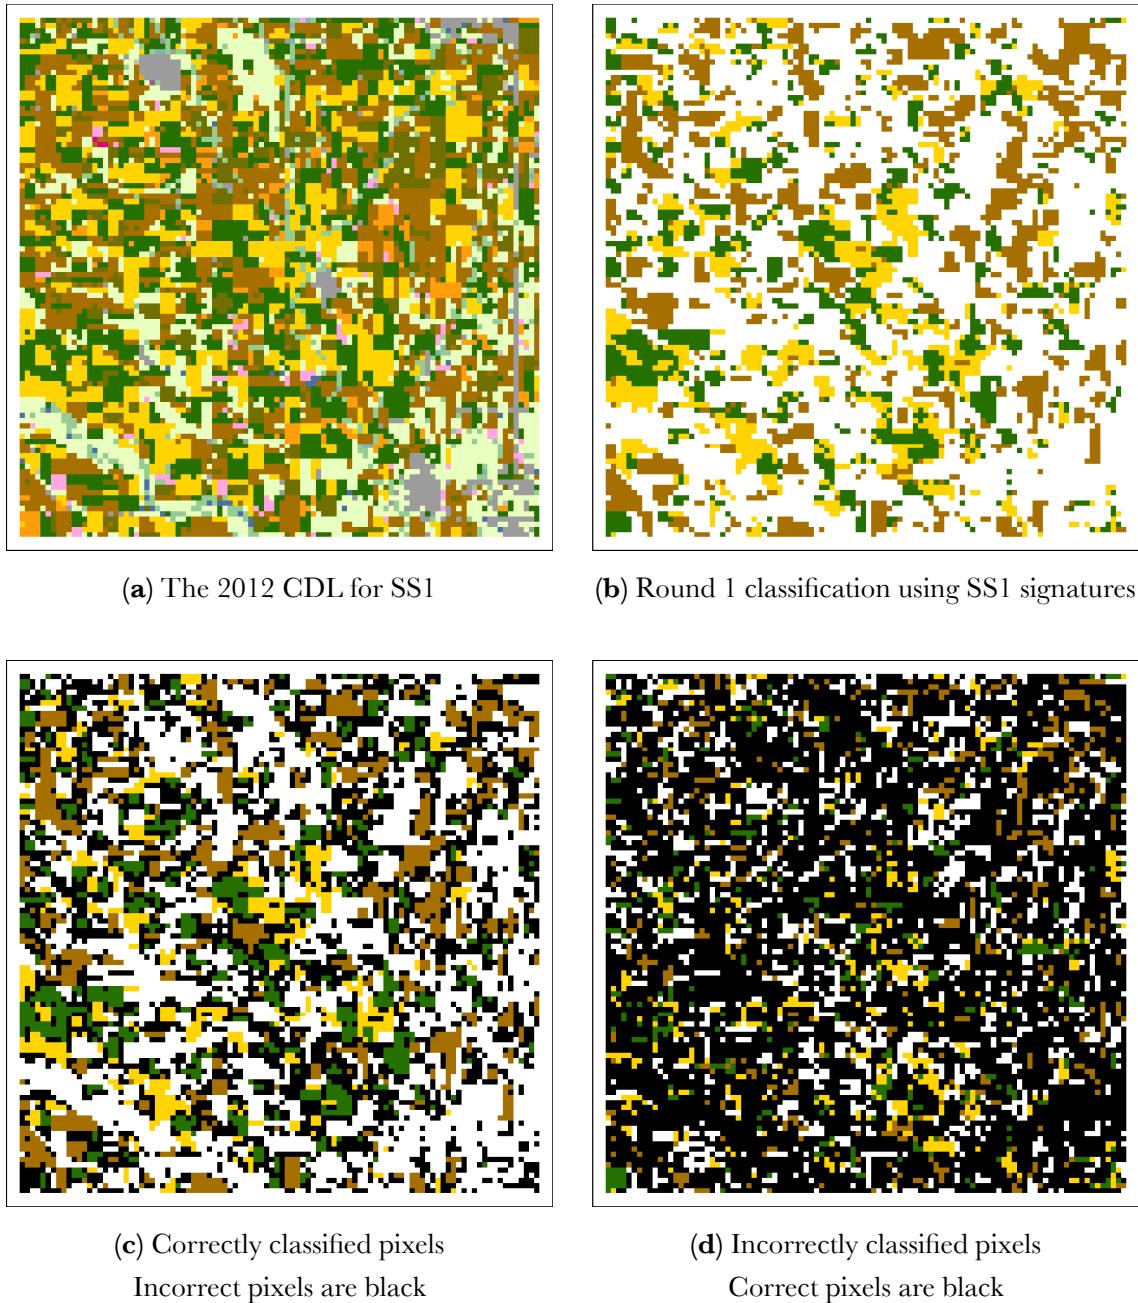

Figure C.3. Round 1 Testing: Study Site 1 Classification.

Corn pixels are shown in yellow, while soy pixels are dark green, and winter wheat pixels are brown. Notice that the classification in (b) looks to do a decent job of capturing where the different crops occur in (a), but (c) and (d) show numerous errors on the edges of fields, and some class confusion.

crops' phenological signatures, and neither of the two crops' references signatures will fit the pixel well. Moreover, the crop which may occupy the majority of the pixel's area may not be the largest contributor a pixel's values. For instance, a mature crop may drive up the VI values for a pixel, even if that crop is in the minority of the pixel. Consequently, I determined I needed to find a way to removed mixels from the classification.

The Testing Process

The first step to removing mixels was to create a vector grid match the MODIS TSI of SS1. Then, I converted the 30-meter CDL raster ground truth dataset to vector polygons. Intersecting these CDL features with the TSI pixel polygons combined the geometries of both. Consequently, pixel polygons that fell within a continuous land cover area were undivided, but mixels were split up into multiple polygons by each land cover class within them. To find all the non-mixels in the study area, I selected all features with an area close to that of a full MODIS pixel from the resulting polygons. Specifically, I chose to select all features greater than or equal to 53,000 square meters in area (or 98 percent of a full MODIS pixel, which is 53,824 square meters). I also manually added two sorghum pixel features that were not selected via this process because of the low number of sorghum pixels retained. The result, shown in Figure C.4, was 1,359 features selected. These features can be thought to represent MODIS pixels that have "pure" signatures: each pixel has only one land cover contributing to its temporal signature, so each should be representative of its class.

To allow me to classify only these pure pixels, I found the centroid of each of the selected pixel polygon features. The subset option of the Find Fit Tool uses a shapefile of point

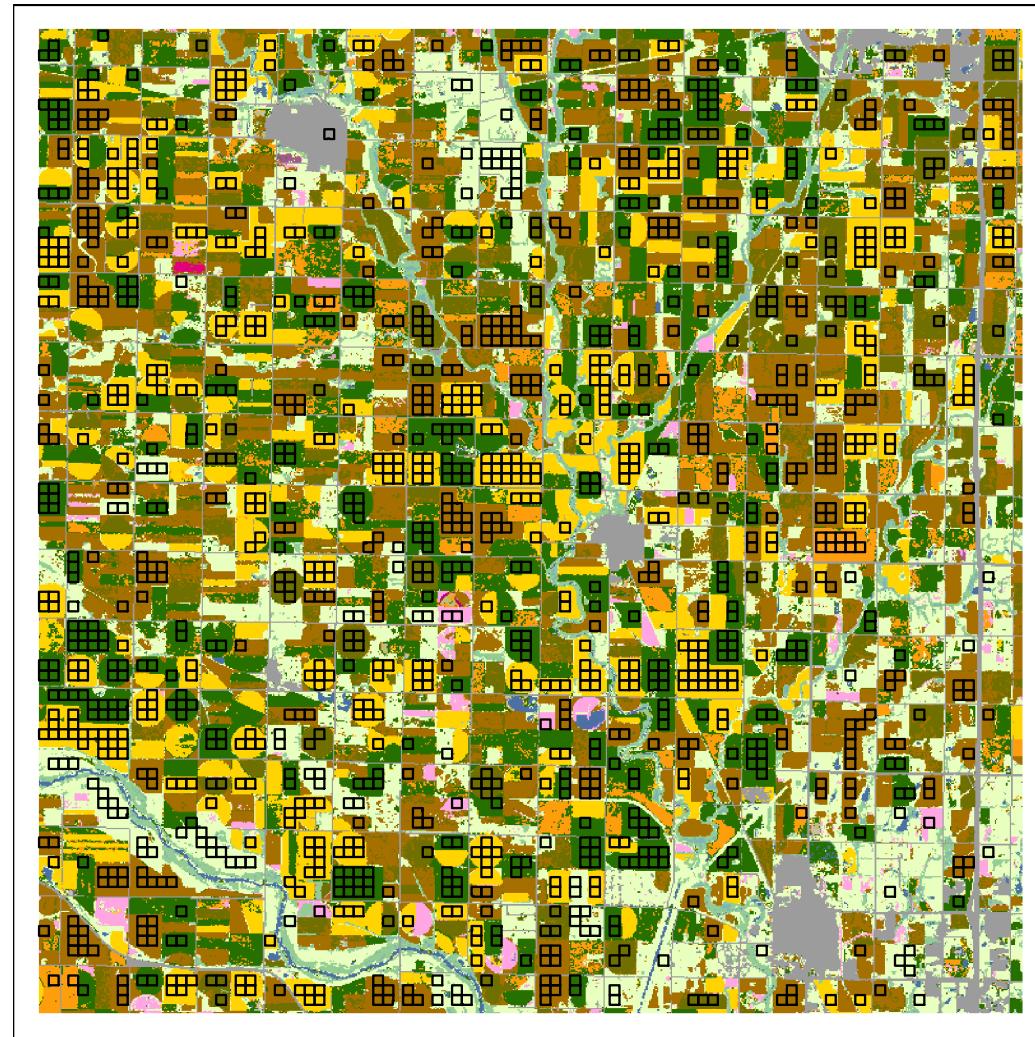

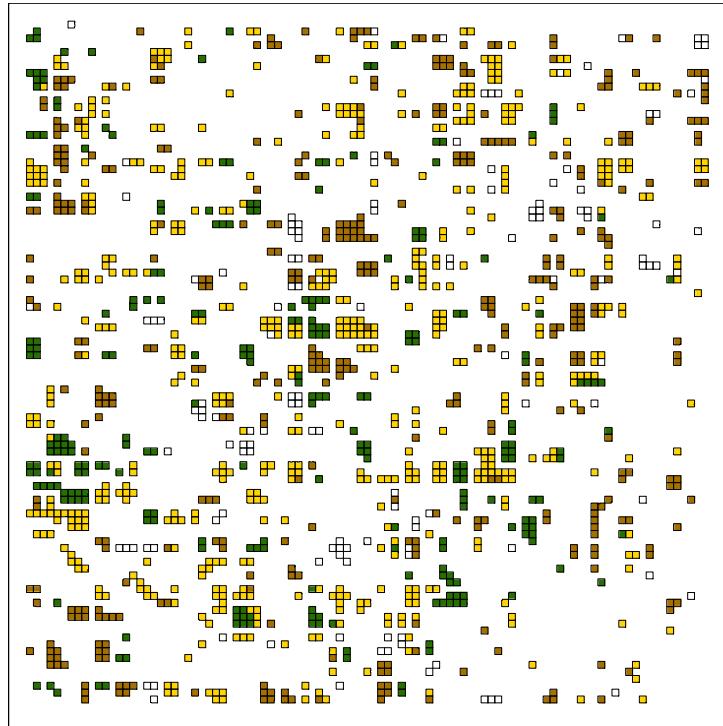

Figure C.4. Pure Pixels Delineated in Study Site 1

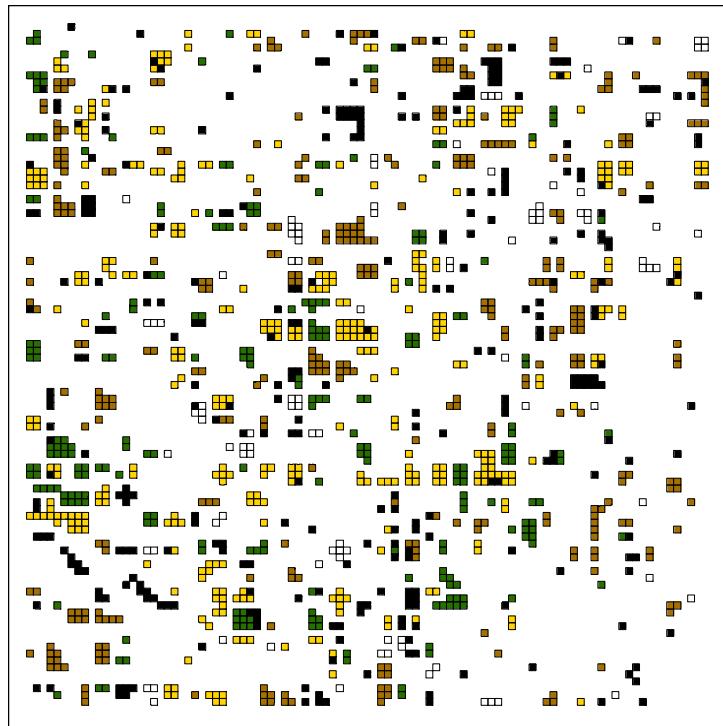

features to create a list of pixel coordinates in the TSI to process. Only these 1,359 pixels were fit with the reference signatures. All the other pixels were assigned NoData (-3000 is the MODIS NoData value). Each of the other classification steps were the same as in Round 1, except the NoData values in the RMSE rasters were ignored by the Classify tool when considering accuracy.

Table C.3. Round 2 Testing: Study Site 1 NDVI Classification of Pure Pixels

		Reference Data					
		Corn	Soy	Wheat	Other	Total	User Acc.
Classified	Corn	358	108	3	79	548	65.34%
	Soy	10	236	0	11	257	91.83%
	Wheat	36	6	348	29	419	83.05%
	Other	10	4	20	101	135	74.81%
	Total	414	354	371	220	1359	
	Producer Acc.	86.47%	66.67%	93.80%	45.91%		Overall Accuracy: 76.75%

bert, and Kastens 2007; Wardlow and Egbert 2008; Masialeti, Egbert, and Wardlow 2010).

To determine the cause of the differences, I plotted the signatures of the pixels sampled to generate each of the reference signatures (shown in Figure C.7 through Figure C.11). Some of these plots showed high variance between the sampled pixels and strange early and late season peaks inconsistent with the accepted temporal signatures for these crops. For example, one abnormally-low valued soy pixel was responsible for pulling down the peak of the soy reference signature. Corn, had extremely variable pixel signatures, which completely mangled its reference signature. Sorghum, among other problems, had very high early season peaks (I have since realized this is likely due to wheat/sorghum double cropping misclassified in the CDL). To correct these and other problems, I realized I needed to change my strategy for identifying the TSI pixels to sample for the reference signatures. Rather than simply finding pure pixels, I needed to ensure the signatures of sampled pixels were representative of the expected crop signature.

C.3 Round 3 Testing: Refining the Reference Signatures

The image analysis software ENVI (Exelis Visual Information Solutions 2014a) has a plotting tool that allows the user to interactively select pixels in a multi band raster and view plots of the pixel values. This tool proved perfect for refining the reference curves. Using it, I could ensure I only sampled crop pixels whose values appeared to match the expected crop signature. The new sample points are shown alongside the old points in Figure C.12. Figures C.13 to C.17 shows the individual signatures of the new sampled pixels for each crop, and the refined reference signatures made from those new sample pixels. In each figure, the original reference signature is shown in gray to illustrate the change. The new soy and corn reference signatures peak higher; soy exhibits its distinctive bell-shaped peak, while corn peaks early, remaining at high VI values before tapering off quickly at the end of its season. The new sorghum signature displays none of the early season peaks, and is much rounder compared to the jaggedness before. Unlike the others, however, the new winter wheat and winter wheat/soy double crop signatures do not differ greatly from the originals, but the originals did not exhibit many issues. Figure C.18 is combined plot of all the new reference signatures so they can be compared to one another.

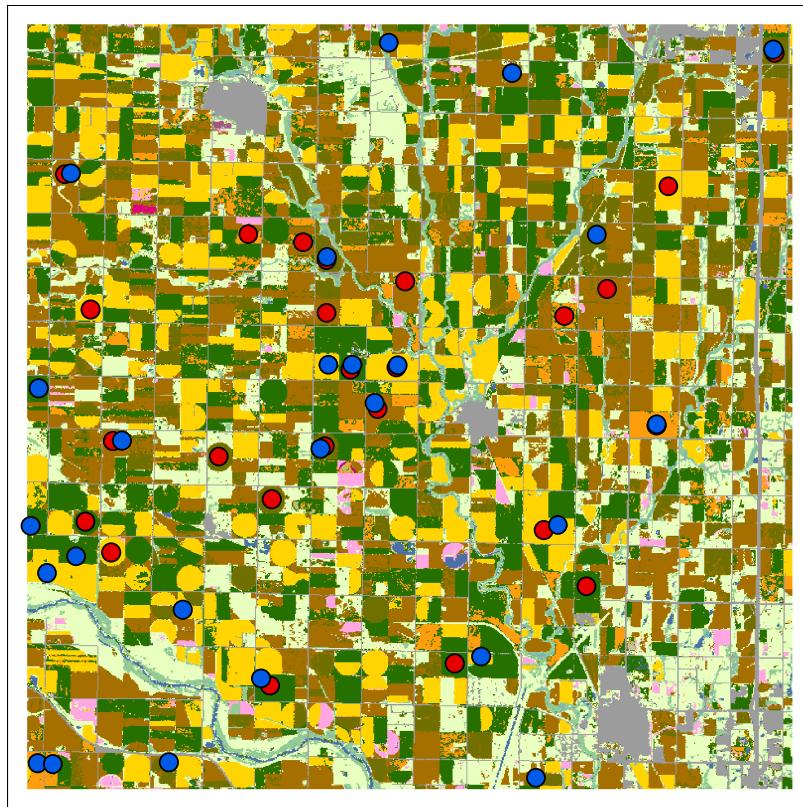

Figure C.12. Points Marking New Pixels Sampled to Create New Reference Signatures

The blue points represent the new pixels sampled to create the new crop reference signatures. The red points are the old points used to create the original crop signatures. Some of the original pixels had good signatures and were used again for the refined signatures.

Figure C.19. Selected Examples of Strange Signatures from Pixels Labeled Corn in the CDL

Each of these signatures was extracted from a pixel labeled corn by the CDL that was not accurately classified in the Round 3 testing. The signatures of pixels 1, 2, 3, and 5 share features on a few key dates, but diverge on others. None of these four is remotely similar in appearance to corn. In fact, the two peaks, around DOY 97 and DOY 161, suggest some sort of double crop rotation. The only signature similar to corn is that of pixel 4, which only departs from the corn reference signature around DOY 257. After that date it sharply increases to an end-of-year peak, suggestive of winter wheat planting for the following year.

Comparing the pixel coordinates of all the incorrect pixel plots, I found many adjacent pixels with similar plot shapes. This finding provides evidence that all pixels in a field generally have the same signature and supports the overall theory behind this method. That is, if all plants of a crop grow under the same conditions, they should have the same temporal signatures.

However, the many different signatures I found within each crop class of the CDL is particularly troublesome. Assuming the truthfulness of the CDL, this suggests that each crop has multiple temporal signatures. Not only does such reasoning conflict with previous research into phenological classification, but is illogical considering the typical growth cycle for crops like corn and soy. The same crops within close proximity should be exposed to essentially equal growing conditions. Variations in planting date may account for slight differences in the temporal signatures. The use of irrigation or application of pesticides, fertilizers, or herbicides may also impart slight disparities between signatures (Wardlow and Egbert 2005; Wardlow, Egbert, and Kastens 2007; Wardlow and Egbert 2008; Sakamoto et al. 2010). However, none of these variables would likely be accountable for the vastly different crop signatures observed.

To get an expert opinion, on 31 May 2014 I e-mailed a few of the signatures plots of incorrectly classified pixels, labeled as corn in the CDL (similar to pixels 1, 2, 3, and 5 in Figure C.19, to Dana Peterson, a research assistant at the Kansas Applied Remote Sensing Program of the Kansas Biological Survey at University of Kansas. She and her colleagues have significant experience working with phenological classifications made using MODIS VI data and the Kansas CDL. Her reply of 1 June 2014 confirmed that the signature types I

sent is likely attributable to double cropping, and that the CDL is not correct in these cases.

The remaining incorrectly classified pixels that did not have the double crop appearance were, predominately, similar to pixel 4 in Figure C.19. These pixel signatures all had an unusual bump in value at the end of the year. Reviewing typical crop signatures plots in the phenological classification literature made me think the end-of-year increase in NDVI of many incorrectly classified pixel may be related to winter wheat planting for the next year's growing season.

To investigate this idea, I used the U.S. Geological Survey Landsat Look online imagery viewer to identify some of these incorrectly classified fields and see how they appeared through time. The fields with the increase in values at the end of the year featured vegetation throughout the winter, and had significant vegetation growth early in the following year, consistent with winter wheat. Moreover, an analysis using the CDL for 2013 showed 172 of the incorrectly classified pixels were planted with winter wheat in fall 2012.

C.4 Round 4 Testing: Different Time Ranges

Deriving the Date Ranges to Test

As many of the pixels this winter wheat bump did not fit the reference signatures within the utilized RMSE thresholds, I wondered what would happen if I changed the date range of the TSI. Instead of beginning and ending the TSI at the start of January, I decided to create a TSI that would include the end-of-year winter wheat bump from 2011 and end before the bump in 2012. Specifically, I selected images from 2011 DOY 305 through 2012

DOY 289.

As by this point I had also returned from my field work in Argentina, I had a bit better idea of how my processing procedure would have to change to classify the Pellegrini imagery. In talking with the locals on Pellegrini, I found that wheat was just one of a number of different grains that were grown in the winter dry season. Moreover, given my visit was in the middle of the summer growing season, I did not have any good way to verify where nor what types of winter crops were grown. To compound the problem, I also learned that, due to the length and flexibility of the summer wet season in Pellegrini, farmers were not limited to double cropping only late summer crops with a winter crop. Instead, any summer crop could be grown with a winter crop. As I only extracted one double crop signature from the Kansas data, the winter wheat and soy signature, I realized I would not be able to use my Kansas signatures to classify an entire agricultural year in Argentina. Rather, I could only classify summer crops. Consequently, I decided to classify SS1 during only the spring and summer months, using MODIS imagery from DOY 97 through DOY 273.

Classification Procedures

The only difference in the processing procedure for these two classification as compared to the previous procedure in Round 3 was that I selected the desired MODIS .hdf files covering each of the date ranges and placed those files in two folders. I then used those folders as the directories for the MODIS .hdf sources when building the two TSIs. I used the same reference signatures as derived in Round 3, and only classified the pure pixels identified in Round 2.

Table C.5. Round 4 Testing: Study Site 1 NDVI Classification of Pure Pixels Using Refined Reference Signatures, 2011 DOY 305 Through 2012 DOY 289

		Reference Data					
		Corn	Soy	Wheat	Other	Total	User Acc.

							Overall Accuracy: 75.06%
							Kappa: 0.63

data again without the sorghum signature, classifying just corn and soy. However, this merely traded confusion between sorghum and soy for confusion between corn and soy, and the overall accuracy was essentially unchanged at 75.3 percent.

In both summer-only classifications, I did find the accuracy increased over the entire year classifications. However, I began to realize that these results were not actually comparable to the previous classification results. Before I had always been finding winter wheat, corn, and soy. However, these results classified corn, soy, and sorghum. To allow a direct comparison between the 2011-2012 and the summer 2012 classifications, I reclassified the 2011–2012 RMSE rasters, looking for corn, soy, and sorghum without wheat. To my surprise, I found the overall accuracy to be more or less the same as classifying just the summer months. Looking more closely at the confusion matrix of this classification (Table C.7 and comparing it with that of the summer 2012 classification (Table C.6 reveals a few discrepancies. In the summer only classification, one can see a significant degree of confusion between sorghum and soy that is not present in the 2011-2012 classification. However, the producer accuracy

Table C.7. Round 4 Testing: Study Site 1 NDVI Classification of Pure Corn, Soy, and Sorghum Pixels Using Refined Reference Signatures, 2011 DOY 305 Through 2012 DOY 289

	Reference Data					
	Corn	Soy	Sorghum	Other	Total	User Acc.
Classified	Corn	389	211	7	69	676 57.54%
	Soy	0	124	3	2	129 96.12%
	Sorghum	0	4	6	0	10 60.00%
	Other	25	15	2	502	544 92.28%
	Total	414	354	18	573	1359
Producer Acc.		93.96%	35.03%	33.33%	87.61%	Overall Accuracy: 75.13% Kappa: 0.62

for soy in the 2011-2012 classification is only marginally better, as soy is instead confused with corn. Looking through the other statistics in the tables, seeming any advantage of one classification over the other is balanced by other inaccuracies. In other words, without a specific reason to choose one over the other, they perform equally.

This result validates that restricting the classification to only the summer months does not have a negative effect when classifying summer crops. In light of this result, and my experience in Argentina, I decided to use the summer-only approach for all subsequent testing.

C.5 Round 5: A Last Ditch Effort to Match the CDL

In attempt to create a classification to match the CDL as best as possible, I used a cluster analysis of the pixels of each of the crops to try to isolate the different signatures I previously identified. This classification process and the subsequent results are those presented in the body of this thesis. To read about the methods, see Chapter 4 on Page 28. The results are

presented in Section 5.4 on Page 44, so I will only briefly summarize my findings here.

Using the clusters for did in fact increase the classification accuracy to 84.4 percent. A map of the classification, Figure 5.5, is on Page 48. The confusion matrix is Table 5.4 on Page 47. Sorghum was not well classified, which may have something to do with the date range used (see the full discussion of the results in Section 6.2 on Page 54). However, it is also possible that the sorghum pixels were not accurately identified by the CDL. The CDL does not have clearly-delineated sorghum fields, but rather a mix of soy and sorghum. Thus, it appears that the USDA's classification method is unable to accurately differentiate between soy and sorghum in some cases. Consequently, sorghum pixels may have been included in the soy clusters, and vice versa. This would mix the temporal signatures and cause confusion in the results.

Of course, the soy and sorghum signatures are rather similar in appearance, and it might be that my method is unable to distinguish them from one another. Even if the CDL has confusion between the two, this may be case. More testing is necessary to determine what might be happening.

Also mentioned in the discussion, specifically Section 6.1 on Page 53, one of the soy signatures had a strange, non-soy-like appearance (Soy_1 in Figure 5.4 on Page 46. I decided to re-run the classifier as before, except I omitted this soy signature. The accuracy did drop, to 81.5 percent, but when I visually analyzed the classification I could see that all the previous errors where non-crop pixels were classified as soy were no longer present. I interpret these results to mean one of two things: (1) some soy fields have signatures quite similar to grassland and pasture areas, or (2) the CDL inaccurately classifies some grassland

or pasture as soy. From my understanding of crop phenologies, and given my experience looking at crop signatures, I believe the latter is more likely.

C.6 Discussion and Conclusions

Are the results still rather low because the CDL has class confusion? That is, might my inaccuracy be compounded because of inaccuracies in the CDL that my classification methods will never recreate? I must posit that my method might actually be more accurate than I can test given the problems with the CDL. However, even if the accuracy of the CDL is 90 percent, as is published, what is the a reasonable accuracy for me to achieve? If my classification were 100 percent accurate, comparing it to the CDL would only result in 90 percent accuracy. Thus, a classification of 80 percent accuracy may indeed be higher relative to the actual ground conditions. Only further testing with confirmed ground truth can really say.

Appendix D

Ideas for Future Testing

Given the practical constraints of this particular project, many aspects of this approach to classification have gone largely or completely untested, and some could have a profound impact on the classification accuracy. I am sure that I have not thought of everything that could be tested or improved, but I have compiled the following list of ideas to help future researchers working with these tools, broken down by each step of the workflow, with general ideas at the end. I have included comments where applicable.

D.1 Reference Temporal Signatures

Idea: How does spatial and temporal variation in the sources used to generate a temporal signature (e.g. multiple study sites and multiple sample years, respectively) effect the accuracy of classifications produced with that signature?

Comment: This question is one that I initially asked and tried to investigate. My findings (presented in

[LINK TO SECTION](#)

), were largely inconclusive due to the numerous problems I have identified. Now that I have refined the method somewhat, this question could be revisited. My hypothesis remains the same: the greater the variations averaged together to create a reference signature, the further that signature gets from an ideal reference which can be transformed effectively to fit pixels of that crop.

Idea: Given the previous question, would another method for combining the signatures of two pixels would be more effective when creating a reference signature?

Comment: I have used two methods to average individual pixel crop signatures. The first, used throughout the work presented in the rest of this thesis, is a simple mean of the values at any given date.

I have also tried using a method something like “fit averaging”: using the same function as is used to find the RMSE values for each reference signature, the time shift and horizontal and vertical differences between two signatures can be found. Dividing each of those transformations by two and applying them to one of the original signatures theoretically creates a new signature halfway between the two original signatures. However, in practice, this resulted in strange curve forms when the signatures averaged were not very similar. It may be that this method deserves a second test using the refined sample points, which all have similar shapes, as this approach may be particularly sensitive to outliers. It could also be that my program to perform this function has errors.

On the subject of outliers in reference signature generation, it may also be worth-

while to test how using a geometric rather than arithmetic mean of the sampled pixels' values might alleviate the effect of outliers.

D.2 Mixels

I am sure brighter minds than mine could come up with better ways to deal with mixels rather than my simple elimination. For instance, perhaps some method of signature unmixing could allow for sub-pixel classification. With the current process of eliminating all mixels, I do have a few ideas to be tested:

Idea: What is the purity threshold before a mixel is too mixed? That is, what percentage of a whole pixel can still be accurately classified?

Comment: In my case, I, perhaps arbitrarily, chose to eliminate all pixels less than 98 percent of a whole MODIS pixel. This allowed me to select just a few more pixels to classify, presumably without any negative impact from the possible 2 percent mixing in those extra pixels. Yet, perhaps I could have chosen much more mixed pixels, or should not have chosen pixels mixed even in the slightest. Finding the percentage threshold where classification is still effective is a key step in making this method more useful.

Idea: Do all land covers contribute equally to the temporal signature of a mixel, or do some land covers have a greater influence on the signature of a mixel? Might the percent mixed threshold discussed above vary depending on the land covers contributing to a mixel's signature?

Idea: Could the classification be used with higher spatial resolution data in such a way to combine the strengths of this classification method with the ability of higher-resolution data to distinguish smaller features? One example of such a method might be to use this process with a low threshold on the RMSE rasters to identify only fields that have a very high probability of being a given crop. Then, those fields could be used in a standard supervised classification process as training sites, much in the same way unsupervised classifiers are used to generate training sites for supervised classifiers.

Comment: This is one of my favorite ideas, and I am very excited about the potential of combining data and techniques like these. I sincerely hope that someone (perhaps myself) will try this idea. I have high expectations for such a combination. Not only would this idea allow for higher spatial resolution classifications to be made, but would also not require the current thresholding step nor ground truth to create a classification.

D.3 The Fitting Process

Idea: How do the bounds on the transformation coefficients change the performance of the algorithm?

Comment: Loosening the bounds on the transformation coefficients would allow a reference temporal signature to better fit pixel signatures which are more dissimilar, but could allow greater confusion between the classes, and could allow reference signatures to fit wholly-unrelated pixel signatures with a low RMSE. Tightening the bounds

would restrict the signature transformation, and may reduce confusion, but could also prevent the algorithm from fitting reference signatures to legitimate pixel signatures, resulting in errors of omission. The bounds as used in my testing were determined almost arbitrarily, being the result of limited preliminary testing and setting them to something that seemed like it worked. I am certain this is one aspect of the tool that requires further optimization and has a large effect on classification results.

Idea: What is the best VI for use with this method?

Comment: From my results I believe NDVI is better suited for use with this method than EVI, the other MODIS-supplied VI. However, many other VIs could be used, and may allow for better accuracy or different use cases.

Idea: How does the mean used to calculate the RMSE change the classification accuracy?

Comment: Based on the advice of my advisor, I tried using a geometric mean for the calculation of the RMSE in the fit algorithm. With this approach, Equation 2.3 becomes:

$$RMSE = \left[\left[\prod_{x=j(0), j(1)}^n (f(x) - g(x))^2 \right]^{\frac{1}{2}} \right]^{\frac{1}{n}} \quad (D.1)$$

I found it to be too insensitive and it resulted in unrealistically low RMSE values. It seemed this mean allowed reference signatures to fit to pixels that should not be classified (they are “other”) in a similar threshold range to pixels which are legitimate. However, with other optimizations to the overall classification process, there may be valuable in formally testing this mean. The Find Fit Tool already has an option to

use a geometric mean instead of an arithmetic mean, so this does not require any programming changes to test.

Idea: Is this the right way to go about comparing a reference signature to an unknown pixel's signature? Would another comparison method be more effective and/or efficient?

Comment: I tried using the RMSE as a comparison as it was shown to work in Brown et al. (2007) and Sakamoto et al. (2010). However, another measure of curve likeness might perform better. I do not know what that method might be, but some brief searches on curve fitting revealed such things as Procrustes distance, dynamic time warping, and Frechet distance. I am interested to see how a different curve comparison would affect the results.

D.4 Thresholding and Classification

The thresholding and classification step is the part of this process I dislike the most. My original intention was to create a method for classifying crops without ground truth, but this part of the process requires ground truth to

Idea: How much difference do different RMSE thresholds for each crop really make in the overall accuracy? If everything else is optimized, can a single threshold value be used for all the RMSE rasters without sacrificing much accuracy.

Comment: Understanding if this is a viable alternative is likely necessary if the

method is to be used with no ground truth as desired.

While I cannot draw any conclusions from these results, I did make some test classifications of the summer 2012 Kansas TSI using the k-means clustering discussed in Section 4.3.4 (Page 34). However, unlike the process documented therein, I set the k-means tool to find ten clusters for each crop.

This clustering produced thirty clusters: ten each for corn and soy, nine for wheat-soy double cropped, and one for sorghum. Processing thirty RMSE rasters with the classification/accuracy tool using just two RMSE value thresholds would theoretically take 0.35×2^{30} seconds—almost twelve years—to complete on my computer. Rather than wait for that process to complete, I decided to use a single threshold across all the RMSE rasters and see what the results would be like.

I stepped through RMSE value thresholds of 400 to 850 by increments of 50. The highest accuracy classification, 71.7 percent, occurred at with a RMSE threshold of 650 across all the RMSE raster. Omitting the wheat-containing reference signatures boosted the classification accuracy to 79.2 percent at the same 650 threshold value. A last test without the sorghum signature proved to be the highest accuracy at 81.0 percent, again with the same RMSE threshold of 650.

Idea: Do the optimal RMSE thresholds vary little, or are they highly variable?

Comment: While I have not been testing this formally, the wide spread of the op-

timal RMSE thresholds that I've identified across all my classifications suggests that the best RMSE threshold values are unique to every circumstance and quite variable.

Idea: Is there a faster way to iterate through the many possible RMSE thresholds than brute force?

Comment: One challenge in the thresholding process is that I have observed local maxima in the classification accuracy. In other words, the accuracy may peak with a certain threshold combination, but that peak may only be a local maxima, and a different threshold combination may allow an even higher accuracy.

Idea: Might the variation within the RMSE values for a signature contain useful information that could be used to find an optimized RMSE threshold value statistically?

Comment: This connects with the previous question. Additionally, if the RMSE thresholds could be determined statistically, then no ground truth would be needed to create the classification.

Idea: If multiple signatures are used for a single crop, each resulting in a separate RMSE raster, should the RMSE rasters for that crop be combined before thresholding using the lowest RMSE for each pixel?

Comment: Barring the realization of a new method for thresholding the RMSE rasters, this question deserves some thought. Processing time increases exponentially with each additional RMSE raster. Taking the minimum value from

a collection of rasters takes a negligible amount of time. Therefore, if all the RMSE rasters for a single crop were of equal validity, this idea would make sense. However, if some of the reference signatures used were not reliable or potentially inaccurate, one would want the thresholding process to eliminate the RMSE rasters of any such signatures by holding them at low RMSE thresholds. Preempting the thresholding process by merging the RMSE rasters of a signature would not allow the RMSE thresholding to weigh the RMSE rasters unequally.

Idea: Can the classification tool also generate a confidence raster, and if so, would it be meaningful? See

REFERENCE IDRISI DOCUMENTATION ABOUT CONFIDENCE
SCORES

for more details.

D.5 General Ideas

Idea: How does the interval of the imagery (number of images used for a given time period) change the effectiveness of the classification? Does using more images (an interval of less than 16 days) allow for a more accurate classification, or for the use of smoothing techniques on the pixel data to help eliminate noise and/or enhance distinguishing features of the crop signatures?

Comment: Sakamoto et al. (2010), whose work has directly informed my own, used

the 8-day MODIS composite images, rather than the 16-day composites, which they resampled to 5-day intervals to get even more detailed data. They also used a wavelet filter on the pixel curves to reduce extraneous noise. Doraiswamy, Akhmedov, and Stern (2006) used a similar approach. I have been operating under the untested assumption the 16-day composites are sufficiently detailed for this analysis, but that may not be the case. The significant advantage of the 16-day composites, however, is that they do not require much preprocessing. 8-day composites are more likely have cloud cover, and are only available as separate bands, not as preprocessed VIs. If such processing were necessary, it could be automated, but would still be additional complexity. Daily data are also available, but that would further increase complexity, as well as significantly increase storage and memory requirements.

Idea: What about using this method with something other than VI data? What if this could be used multi-dimensionally, with multiple bands? With different data, e.g. higher spatial resolution data, what could be other applications of this method?

Comment: I don't have any use cases in mind when I ask this question. I merely pose it in an attempt to spark an idea for anyone working with different applications.

D.6 Concluding Remarks

The testing I've completed has largely been to demonstrate that the tools I have developed to perform this type of classification are functional and that this hypertemporal signature-fitting approach may be effective for certain remote sensing applications. As one can see by the list above, a lot of work remains to increase the understanding of how different parameters affect fitting and classification. This study is just the beginning of a large body of potential research, which I believe will only be of increasing importance as earth-observing sensors become more numerous and high spatial and temporal resolution data become more commonplace.

Appendix E

Notes on the CDL

Some of the test results and opinions I present throughout this document may lead the reader to question the USDA CDL as source of ground truth data. I believe everyone should approach data critically, and I do not feel badly for the criticism I present of this dataset. My critique is based on my own experience with the data and rumors that have made it to me about the trouble of others with these data. Some have expressed reservations about the published accuracies.

Despite all this, I must make three disclaimers about my opinions.

First, I must admit, all my experience has been with the CDL in Kansas. I cannot speak to the accuracy of CDL in other states. I have heard that some other regions are less problematic, though without evidence supporting either view. Perhaps this is the case, and users should have few problems in other areas.

Secondly, I must also acknowledge my study sites were fairly small, and I only worked closely with the CDL in study site 1 (see Figure C.1, which might happen to be an anomalous area with a lower-than-average accuracy. Again, other areas may

not have the problems I experienced.

Thirdly, I do not have a way to quantify the problems I have observed or to verify the CDL is wrong in the ways I believe it is. Consequentially, all the errors I've found may be within the accuracy range as published, and I should not be as critical of the dataset as I am.

In all, the CDL is a fantastically ambitious dataset, and I do not want to suggest that the USDA has failed. Even if the data have problems, the USDA are classifying the entire continental United States, which has extremely variable conditions and an incredible variety of land covers. That the USDA can achieve any reasonable classification at all is impressive.
